MICROSCOPIC OBSERVATIONS OF LARVAL *OSTREA CIRCUMPICTA* (BIVALVE: OSTREIDAE) IN BROOD CHAMBERS

DO-HYUNG KANG,¹ SE-JAE KIM² AND KWANG-SIK CHOI^{1*}

¹School of Applied Marine Science, College of Ocean Science, Cheju National University, 1 Ara I-Dong Jeju 690-756, Republic of Korea; ²Department of Life Science, Cheju National University, Republic of Korea

ABSTRACT This study is the first report of the microscopic features of larvae and gonads of *Ostrea circumpecta* collected in Jeju, Korea. Female oysters brooded larvae at the early veliger stage (115–135 μ m) in the infrabranchial chamber. Larvae in this chamber displayed a well-developed velum covered with long and short cilia; the adductor muscle was incompletely developed. The digestive system of the larvae, including the mouth, esophagus, stomach, digestive gland, and intestine, was identifiable in histologic preparations, indicating that the veliger larvae in the brood chamber were capable of feeding using the velum and cilia. Diameters of ripe eggs in the ovary ranged from 67–120 μ m. Most female oysters collected in June 2001 were spawning or absorbing whereas most of male oysters were spent or sexually inactive.

KEY WORDS: ostreidae, *Ostrea circumpecta*, reproduction, larval morphology, brood oyster, Korea

INTRODUCTION

Oysters of the genus *Ostrea* are brooders, releasing larvae instead of gametes during spawning (Buroker 1985, Ó Foighil & Taylor 2000). Gametes of brood oysters are fertilized at the ctenidia, and the embryos are released into the branchial chamber of females. In this chamber, the larvae undergo pelagic development, including trochophore and veliger stages (Strathmann & Strathmann 1982, Mackie 1984, Ó Foighil & Taylor 2000). Veliger larvae in the chamber are characterized by velum covered with cilia that are used for locomotion and feeding (Elston 1999, Chaparro et al. 1999 & 2002). Swimming veliger larvae are often observed in suprabranchial or infrabranchial chambers (Chaparro et al. 1993). However, brooding oyster larvae are often kept in interlamellar spaces or brood sacs and are immobile (Mackie 1984, Tankersley & Dimock 1992).

Microscopic examination of larvae provides valuable information on feeding type, developmental mode, planktonic period, and larval settlement (Strathmann & Leise 1979, Pechenik 1986, Strathmann et al. 1993, Chaparro et al. 1999). Histology has been widely and extensively used to examine the larval structure and development of marine bivalves (Howard & Smith 1983, Elston 1999). In addition, video cameras and endoscopes are often used in microscopic observations of marine bivalve larvae (Ward et al. 1991, Strathmann et al. 1993, Tankersley & Dimock 1993, Bosch & Slattery 1999, Elston 1980, Chaparro et al. 1999&2002).

Ostrea circumpecta is abundant on rocky intertidal to subtidal zones of Jeju Island (Kwon et al. 1993), Korea, where salinity remains high and stable all year (Lee et al. 2000). Like other oysters of the genus *Ostrea*, this species is a brooder and is widely distributed in southern Japan, China, and Korea (Hirase 1930, Bernard et al. 1993, Kwon et al. 1993). Despite its abundance, few studies have investigated the ecology and reproductive biology of *O. circumpecta* (Bae & Bae 1972, Yang 1999&2001). Here, we provide the first report of the microscopic features of the gonads and larvae of *O. circumpecta* in sexually mature individuals.

MATERIALS AND METHODS

Munseom, an uninhabited island located off the southern coast of Jeju (33°13' 25"N, 126°33' 58"E), is well known for its high species diversity and richness of marine biota (Je et al. 2002, Fig. 1). The island characterized by volcanic rocky intertidal and subtidal zones that are subjected to strong wave action. The rocky substrata are enriched with sessile fauna such as oysters, barnacles, and numerous species of anthozoans. In particular, *O. circumpecta* heavily encrusts the subtidal cliff at depths between 3 and 6 m. Surface water temperatures and salinity in this area vary from 16 °C to 22 °C and from 32.2–34.4 psu annually (Choa & Lee 2000, Lee et al. 2000). Due to the influence of the warm Kuroshio current, surface water temperatures during winter are several degrees higher than in northern Jeju.

O. circumpecta were collected in June 2003 by SCUBA diving at depths between 3 and 5 m. Oyster tissues were fixed in Davidson's fixative, and longitudinal sections were made along the middle of the body of fixed specimens (Fig. 2A) using standard histologic methods. Microscopic images of oyster eggs and larvae in brood chambers were converted to digital image using a digital camera installed on the microscope. The size of eggs and larvae were then measured from the images using image analysis software (Kang et al. 2003).

RESULTS

Figure 2 shows a female *O. circumpecta* collected in June 2003. This species has a relatively large adductor muscle and gills compared with nonbrooding oysters. The mantle is composed of two layers with thick mantle lobes. We found no hermaphroditic individuals in this study. Figure 3 shows numerous early veliger larvae in the infrabranchial chamber. The visceral masses of the larvae were filled with coelomic fluid in the coelomic cavity. The larvae were approximately 115–135 μ m long, and we observed no physical connections between female oysters and larvae. No obvious structural changes for holding larvae were found in the gills. Figure 4 shows intact larvae isolated from the chamber. The upper part of the velum was covered with two types of cilia: long outer preoral cilia (i.e., OPC, Chaparro et al. 1999), 20–40 μ m long and short inner preoral cilia (IPC), 5–10 μ m long.

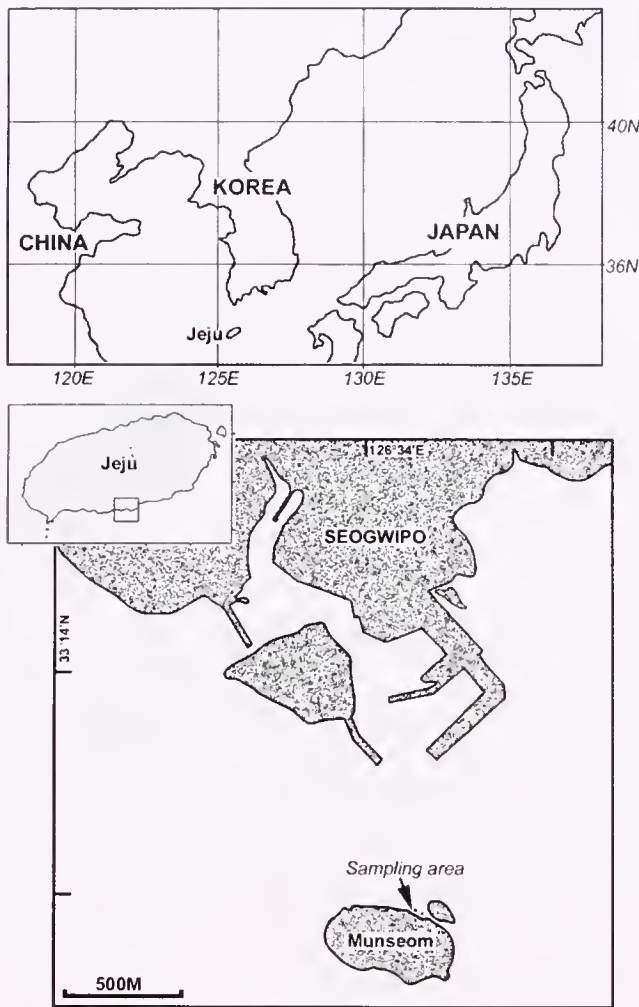

Figure 1. Sampling location.

Figure 2. *O. circumpicta*. General morphology of an adult. Bold parallel lines in the middle of the body show the location where the tissue for histologic cross-section was collected.

Figure 3. Photomicrograph of larvae in the infrabranchial chamber of *O. circumpicta*. F: filament; L: larvae; Im: interlamellar muscle.

Figures 5 and 6 illustrate the internal structure of early veliger larvae. The mouth is located at the edge of the lower part of the velum, and the oral opening lead to the esophagus. The stomach is visible at the end of the digestive tract. The larval stomach, digestive gland, and intestine form the digestive system. Although it is not completely developed, the adductor muscle is identifiable in the larvae. Cilia are mainly located on the periphery of the velum; sensory cilia are also found on the apical plate located at the center of the velum. Some particles were identified in the digestive gland that were believed to be ingested diatoms (Kohn, personal communication).

Figure 5. Longitudinal section of larval *O. circumpicta*. Cl, cilia; Dg, digestive gland; Es, esophagus; Fp, food-like particle; Gr, gill rudiment; In, intestine; Mo, mouth; Mn, mantle; Rm, retractor muscle; St, stomach; Vel, velum.

Figure 7 shows a longitudinal section of female oyster whose follicles are packed with ripe eggs (see Fig. 7A). The diameter of egg nuclei ranged from 16–35 μm , with a mean of 26 μm ($n = 29$). Egg diameter ranged from 67–120 μm , with a mean of 89 μm ($n = 60$). However, most ripe eggs were ready for discharging from the follicles 90–110 μm in diameter. Some degenerating ova

were surrounded by hemocytes, indicating that the eggs are phagocytosed by hemocytes (see Fig. 7B). Nine male oysters analyzed in this study exhibited spent testes or were in sexually inactive (see Figs. 7C, 7D), indicating that males spawned earlier than females.

DISCUSSION

In marine bivalves, fertilization and development of larvae is either external or internal (Sastry 1979, Strathmann & Strathmann 1982, Olive 1985, Levitan & Petersen 1995). Oysters of the genus *Crassostrea* broadcast eggs and sperm in the water column, and fertilization and subsequent larval development occurs externally. In contrast, in oysters of the genus *Ostrea*, egg fertilization takes place internally in the gills (Andrews 1979, Harry 1985, Chaparro et al. 1993, Ó Foighil & Taylor 2000). The embryos or larvae are then raised in the mantle cavity, suprabranchial, or infrabranchial chamber of the female (Buroker 1985, Chaparro et al. 1993, Ó Foighil & Taylor 2000). In this study, larvae were located mostly in the infrabranchial chamber (see Figs. 2, 3), indicating that *O. circumpicta* uses its gills as a brooding chamber, as has been observed in other brooding oysters of the genus *Ostrea*.

Early veliger larvae located in the infrabranchial chamber showed a well-developed velum covered with cilia (see Figs. 5, 6). The presence of a ciliary ring around the velum is one of the key characteristics of veliger larvae (Waller 1981, Beauchamp 1986, Strathmann et al. 1993, Chaparro et al. 1999). Cragg (1989) suggested that a well-developed velum with cilia is an adaptation for prolonged planktonic life in the water column. The velum also plays a key role in feeding during the larval period (Hadfield et al. 1997, Klinzing & Pechenik 2000, Chaparro et al. 2002). Larvae in the brood chamber observed in this study exhibited a well-developed digestive system that included the mouth, esophagus, stomach, digestive gland, and intestine (see Fig. 5). Longitudinal section of the larvae also showed some food-like particles in the digestive gland (see Fig. 5), suggesting that the larvae are involved in feeding activities (Elston, 1999). Chaparro et al. (1993) experi-

Figure 6. Frontal section of larval *O. circumpicta*. Ap, apical plate; Lcl, locomotory cilia; Dg, digestive gland; Es, esophagus; Gr, gill rudiment; In, intestine; Mn, mantle; Rm, retractor muscle; Scl, sensory cilia; Sr, shell rudiment; St, stomach; Vel, velum; Vc, visceral cavity.

mentally fed the veliger larvae of *O. chilensis* with plastic particles (2–10 μm in diameter), and the particles were later found in the digestive system. Their study indicated that the veligers were actively involved in feeding activities in the brood chamber. Thus, it is believed that *O. circumpicta* veliger larvae also feed on food particles available in the brood chamber, as was observed in *O. chilensis*.

The size of the *O. circumpicta* egg measured in this study varied from 67–120 μm, which is somewhat larger than the eggs of nonbrooding oysters such as *C. gigas* or *C. virginica* (40–58 μm, Gallagher et al. 1986, Arakawa 1990, Choi et al. 1993, Brousseau 1995, Lango-Reynoso et al. 2000, Kang et al. 2003). The relatively larger egg size of *O. circumpicta* suggests that these oysters produce lecithotrophic eggs, like *O. edulis*, *O. denselamellosa*, or *O. lurida* (DiSalvo et al. 1983, Mackie 1984, Arakawa 1990). DiSalvo et al. (1983) reported that *O. chilensis* larvae in Chilean waters do not ingest food particles when reared outside the brooding chamber, strongly indicating that *O. chilensis* larvae are truly lecithotrophic. In contrast, Chaparro et al. (1993; 1999) used an endoscope to observe veligers of *O. chilensis* (290–300 μm) actively feeding on food particles available in the brood chamber that experimentally provided. The authors concluded that *O. chilensis* larvae are planktotrophic, because they have a complete digestive

system and feed on food particles in the chamber. The *O. circumpicta* larvae observed in this study were 115–135 μm long (i.e., slightly larger than mature eggs [90–110 μm]), indicating that the larvae were in the early veliger stage. Food-like particles found in the digestive system of *O. circumpicta* veliger larvae in this study suggest that the larvae are planktotrophic in the brood chamber.

In conclusion, we observed the larval development of *O. circumpicta* in the infrabranchial chamber using histologic preparations. Ripe and degenerating ova in the gonads and early veliger larvae in brood chamber observed in late June indicated that late June, when water temperature reaches 22 °C, is the spawning. A well-developed velum and digestive system suggested that the larvae are capable of swimming and feeding inside the brood chamber.

ABSTRACT Since 1997, high mortality episodes of cultured oysters have occurred in Bahía Falsa, México. Studies on the possible association of these mortalities with pathogens have showed some similar characteristics to those found in the Portuguese oyster *Crassostrea angulata* and the Japanese oyster *Crassostrea gigas* infected by an iridoviridae-like particles in the lately 1960s. This infection was named gill necrosis virus infection (GNV). In a recent study, we could not find any virus using transmission electron microscopy (TEM) in adult oysters with clinical and histologic signs similar to those described for GNV. However, new TEM images showed the presence of viral particles in eroded gills of oysters. Morphologic characteristics, such as thin-walled icosahedric shape, the presence of capsids in an extension of the nucleus or in a vacuole and size varying from 80 to 90 nm suggest that the viruses belong to the Herpes viridae family. This virus could be involved in the mortality episodes in the Bay and it is different to those described as causal agent of GNV.

KEY WORDS: *Crassostrea gigas*, herpes-like virus, mortality, gill erosion, oyster disease

INTRODUCTION

In a recent study on the possible association of high mortality outbreaks of the Pacific oyster *C. gigas* cultured in Baja California and other states of NW Mexico with a pathogenic agent (Cáceres-Martínez & Vasquez-Yeomans 2003), we found some clinical and histopathologic evidence similar to those described for gill necrosis viral infection (GNV) recorded in the Portuguese oyster *C. angulata* and to a lesser degree in the Pacific oyster cultured in France, Great Britain, Spain, and Portugal between 1966 and 1967 (Marteil 1969, Comps 1988). Previously, we did not detect the iridovirus-like the causal agent of GNV, using transmission electron microscopy (TEM), possibly because the sample process, the status of the gill tissues of surviving oysters (wound repair), and/or difficulties in finding the viral agent in fixed tissues (Cáceres-Martínez & Vasquez-Yeomans 2003). However, new TEM analyses of more samples have detected herpes-like virus particles.

MATERIALS AND METHODS

A sampling carried out in November 2000, of 10 adult oysters (Mean 89.3 ± 7.7 mm shell length), from an area of the Bahía Falsa, Baja California ($116^{\circ}00'W$, $30^{\circ}25'N$) where mortalities were common, were reviewed and those showing highly eroded gill tissues (Cáceres-Martínez & Vasquez-Yeomans 2003) were selected for TEM examination. Small pieces of tissue were cut from the eroded area of the gill and fixed in 3% glutaraldehyde in 0.1 M sodium cacodylate buffer, pH 7.8, for 4 h at 4 °C. Fixed tissues were washed for 12 hours at 4 °C in the same buffer and cut into 1-mm³ pieces. These pieces were then postfixed in buffered 1% OsO₄ for 4 hours at 4 °C, dehydrated through a graded series of ethanols and embedded in epoxy resin. Sections (90 nm thickness) were cut and stained with 5% uranyl acetate for 30 minutes,

then observed with TEM operated at 75 kV in the Instituto de Investigaciones Marinas from Vigo, Spain.

RESULTS AND DISCUSSION

Viral particles were found in all samples ($n = 10$) of eroded gill analyzed in this study. The morphologic characteristics of the

Figure 1. Viral particles showing the pentagonal shape of the capsids (large arrow), thin wall (small arrow), and core (C). Size variations are also observed.

Figure 2. Viral particles (large arrow) in an extension of the nucleus or in a vacuole (small arrow) of the infected cell.

viral particles including capsid shape, presence of a thin wall, size range (Fig. 1), and presence in an extension of the nucleus or in a vacuole of the infected cell (Fig. 2) suggest that they are closely related to Herpes virus (virions enveloped, slightly pleomorphic, spherical, 120–200 nm in diameter). Surface projections of envelope distinct spikes were dispersed evenly over all the surface.

Nucleocapsid surrounded by the tegument that consists of globular material, which is frequently asymmetrically distributed and may be variable in amount. Nucleocapsids were sometimes penetrated by stain (although the intact envelope was impermeable to stain) 100–110 nm in diameter.

Nucleocapsids appeared to be angular and surface capsomer

arrangement obvious. There were 162 capsomers per nucleocapsid (capsomeres hexagonal in cross-section with a hole running half-way down the long axis). The core consisted of a fibrillar spool on which the DNA is wrapped, and the ends of the fibers are anchored to the underside of the capsid shell. Incomplete virus particles often present, are capsids lacking the envelope. Virions contain one molecule of linear double stranded DNA (van Regenmortel et al. 2000). Based on this description of the Herpes viruses, the particles shown in Figures 1 and 2 can be described as herpes-like. There were no particles in the main part of the nucleus and no virions in the cytoplasm. Some capsids were variable in size and thin-walled.

Herpes and herpes-like viruses have been recorded in turtles, carps, ictalurids, frogs, and other aquatic organisms (Buchanan & Richards 1982). In oysters there are several records of herpes or herpes-like viruses around the world (Table 1), and these virus infections in bivalves seem to be ubiquitous (Le Deuff & Renault 1999). All these herpes-like viruses have been described in larval stages and young spat with the exception of adult *Ostrea angasi* in Australia (Hine & Thorne 1997) and possibly adult *Crassostrea virginica* in Maine USA (Farley et al. 1972). However, Farley et al. did not mention the age or size of the infected oysters. Studies on the development of molecular analysis to detect the herpes-like virus in oyster larvae and juveniles have been carried out (Le Deuff & Renault 1999, Renault et al. 2000, Renault & Arzul 2001). Interspecies transmission also has been studied (Arzul et al. 2001a, Arzul et al. 2001b). More recently, Arzul et al. (2002) detected the herpes-like virus in a symptomatic *C. gigas* adult using molecular techniques, including PCR and in situ hybridization (ISH). These authors suggest that this virus may persist in its host after primary infection, and a comparison between adult oysters and infected spat indicated that the spat contain higher amounts of virus DNA. They concluded that viral replication appears less common in adults than in spat. In contrast, our results (Cáceres-Martínez & Vásquez-Yeomans 2003) and those shown in this study, suggest the connection of a herpes-like virus in gill tissue of adults *C. gigas* with clinical signs, histologic alterations, and high mortality episodes. To our knowledge, this is the first record of herpes-like viruses by TEM in adult oysters.

More research is being conducted to further characterize the virus and to determine the influence of environmental factors on the development of the disease in larvae, juveniles, and adults.

TABLE 1.
Herpes-like virus infection in oysters.

Host	Growth Stage	Tissue	Mortality	Name of the Disease	Locality	Reference
<i>Crassostrea virginica</i>	Not mentioned, possibly adult	Haemocytes		Unnamed	Maine, USA	Farley et al. 1972
<i>Crassostrea gigas</i>	Larvae	Connective and mantle epithelium		Unnamed	Northern France	Nicolas et al. 1992
<i>Crassostrea gigas</i>	Larvae	Entire larvae	60–100%	Unnamed	Auckland, New Zealand	Hine et al. 1992
<i>Ostrea edulis</i>	Young spat (5 months old)	Connective, around digestive tubules	90%	Herpes-like infection	Brittany, France	Comps & Cochenne 1993
<i>Crassostrea gigas</i>	Young spat (3–7 months old)	Connective in the gills, mantle and around digestive tubules	80–90%	Unnamed	France, Atlantic Coast	Renault et al. 1994
<i>Ostrea angasi</i>	Adults			Unnamed	Australia	Hine and Thorne 1997

Experimental infections by cohabitation and by injection of a homogenate of eroded gill tissues from symptomatic oysters are being carried out to confirm the role of these herpes virus-like particles as the cause of these mortalities.

ACKNOWLEDGEMENTS

The authors thank anonymous herpesvirus structural expert for his help in the ultrastructural identification of the virus and Dra.

Carmen Paniagua Chávez for suggestions to the manuscript and help in translation. SAND ELIMINATION BY THE ASIATIC HARD CLAM *MERETRIX MERETRIX* (L.): INFLUENCES OF TEMPERATURE, SALINITY AND SEASON

KAREN K. Y. LUI¹ AND KENNETH M. Y. LEUNG^{1,*}

¹The Swire Institute of Marine Science and Department of Ecology & Biodiversity, The University of Hong Kong, Pokfulam, Hong Kong, China

ABSTRACT Clams, being filter-feeders that burrow into sand, tend to accumulate sand in their body tissues. Depuration reduces the clams' gut contents and eliminates sand from different body fractions, providing some cleansing and ensuring that they are safe for human consumption. The Asiatic hard clam *Meretrix meretrix* (Bivalvia: Veneridae) is a commercially important species inhabiting sand flats of Hong Kong and Southeast Asia. In this laboratory study, the effects of temperature and salinity on the rate and profile of sand elimination in *M. meretrix* were studied during winter and summer using a 2 × 2 factorial design (i.e., two temperatures 20°C and 30°C, and two salinities 15‰ and 30‰). Sand removal rate was measured in terms of a decrease in inorganic content (i.e., ash) over a 72-h period. In general, sand was removed from the gut and body tissues and transferred to the external body fluid for subsequent discharge to the ambient water. *Meretrix meretrix* exhibited significantly lower sand removal rates in summer than in winter across all treatments, whereas the highest sand removal rate was observed at 20°C and 15‰ in both seasons. The sand removal rate of *M. meretrix* is, therefore, not only affected by temperature and salinity, but also strongly associated with natural, seasonal, effects. These findings have important implications for optimizing conditions for sand elimination of this species for the shellfish industry in Asia.

KEY WORDS: depuration, salinity, sand elimination, season, temperature

INTRODUCTION

Sandy shore bivalves burrow into sand as an adaptation to protect themselves from wave impact, temperature fluctuations, desiccation, and predation (Nybakken 1997). As filter feeders, they feed during high tide using their siphons, which extend to the sand surface to collect microscopic organisms and particulates from the water column (Morton 1979). Ingested particles, containing both organic and inorganic matter, are either digested in the gut or expelled as faecal pellets (Hylleberg & Gallucci 1975, Ruppert & Barnes 1994). In addition sand particles, together with other unwanted particles such as viruses, bacteria, and pollutants, will be trapped in different organs such as the gills, gut, and adductor muscles (Richards 1988, Savari et al. 1991, Sobsey & Jaykus 1991, Somerset 1991, Ho & Kim 1995, Ariza et al. 1999). When the clams are sold for human consumption, the tissues that contain sand can be unpleasant to eat and also pose a health risk. As a common practice the clams are, therefore, allowed to clean themselves in clean seawater (i.e., depuration) to remove the sand in their body (Richards 1988, Savari et al. 1991).

In bivalves, significant effects of salinity have been reported on mortality (Mane 1978, Morton & Chan 1990), growth (Robert et al. 1988, Hutchinson & Hawkins 1992), and cardiac and siphonal pumping activity (Akberali & Davenport 1981). Salinity is especially important in controlling the effectiveness of depuration by sandy shore bivalves. Richards (1988), for example, demonstrated that salinities between 22‰ and 31‰ were optimal for microbial depuration by the hard clam *Mercenaria mercenaria* (L.), soft-shell clam *Mya arenaria* (L.), and hen clam *Venus gallina* (L.).

Apart from salinity, the depuration rate of bivalves is also influenced by water temperature, suggesting that it may be associated with temperature-dependent metabolic activities. Previous studies have shown that growth (His et al. 1989), respiratory responses (Hicks & McMahon 2002), and filtration rate (Walne 1972) of bivalves are temperature-dependent. Richards (1988) found that the depuration of viruses by the hard clam *Mercenaria*

mercenaria (L.) was improved by increasing temperature, and a similar result was observed in a study on the elimination of coliphages by the mussel *Mytilus edulis* (L.) (Power & Collins 1990). Additionally, Richards (1988) investigated the seasonal variation of microbial depuration by temperate clams in terms of the combined effect of salinity and temperature and revealed that viruses were more effectively depurated from the clams during the summer and fall months than during the winter.

Although the depuration of pathogens (e.g., viruses; Carter & Cantelmo 1990, Ho & Tam 2000), soluble pollutants (e.g., hydrocarbons and heavy metals; Denton & Jones 1981, Jovanovich & Marion 1987, Savari et al. 1991, Reinfelder et al. 1997, Ariza et al. 1999), and phytotoxins (Blanco et al. 2002) in bivalves has widely been studied, information on the elimination rate of insoluble, sand-like particles in clams and cockles is scarce. Indeed, there are only a few reports on sand elimination rates in mussel, clam, and cockle species in relation to their storage and handling in the shellfish industry (De Voys 1987, Richards 1988, NSSP 1990, Somerset 1991).

The current study was therefore designed to investigate the rate of sand elimination by the commercially important, Asiatic hard clam *Meretrix meretrix* (L.) in clean seawater at four different temperature/salinity regimes during winter and summer, respectively. The results from such a study are important for optimizing conditions for sand elimination of this species for the shellfish industry in Asia.

MATERIALS AND METHODS

Sampling and Experimental Design

Meretrix meretrix is one of the largest clam species among the Venus-shells (Veneridae) and very common on sheltered sand flats in Hong Kong, South China, India, Vietnam, Thailand, and the Saudi Arabian Gulf (Morton & Morton 1983, Jayabal & Kalyani 1986, Nhan et al. 1999, Vazquez et al. 1991). As a commercially important clam species in Asia, it has widely been cultured in China and Thailand (Ho & Zheng 1994, Ho & Kim 1995).

In the current study, adult *M. meretrix* were randomly collected

*Corresponding author. E-mail: kmyleung@hkucc.hku.hk

from Shui Hau in Lantau Island, Hong Kong (Grid reference: 22°13'N, 113°55'E) during low tides in winter (24 February 2003; 75 individuals; shell length: 50.01 ± 4.13 mm, mean \pm SD) and in summer (5 June 2003; 75 individuals; shell length: 54.9 ± 7.3 mm). Clams were collected using a specially constructed clam-rack commonly used by fishermen in Hong Kong and South China (Morton & Morton 1983).

Hong Kong has a strongly seasonal, monsoonal climate with a hot, wet summer and cool, dry winter (Kaehler & Williams 1996). Seawater temperature and salinity were measured using a thermometer and a refractometer (ATGAO, S/Mill-E, Tokyo, Japan). The seawater temperature and salinity in the field were 15.0°C and 32.0‰ in winter and 29.0°C and 14.0‰ in summer. Such a considerable difference in salinity between the two seasons was mainly due to the close proximity of the site to the Pearl River estuary, which receives a huge amount of freshwater input during summer (Morton & Wu 1975). The collected clams were transferred to the laboratory within 2 h of collection. On arrival, the clams were divided into four groups and held in 1 L aerated glass tanks filled with 500 mL of artificial seawater (Kent Marine Salt, Kent Marine Inc., Acworth, Georgia) at the same salinity level as measured at the collection site and at room temperature (20°C).

The experimental ranges of temperatures and salinities were based on the natural ranges in the environment (Morton & Wu 1975, Morton & Morton 1983). The clams were acclimatized to four combinations of two temperatures ($20 \pm 0.2^\circ\text{C}$ and $30 \pm 0.4^\circ\text{C}$, mean \pm SD) and two salinities ($15 \pm 0.8\text{‰}$ and $30 \pm 0.4\text{‰}$). The water temperature of the 30°C treatments was adjusted by increasing 4°C every 3 h using a water bath with a temperature controller, whereas the 20°C treatments were maintained at room temperature. Salinity was adjusted by decreasing or increasing values by 5‰ every 3 h until the desired levels were reached. This was achieved by renewing the seawater with artificial sea salts. A control group of 15 individuals was randomly selected at the beginning of the experiment to determine the initial inorganic content of the clams prior to depuration.

For each treatment group, there were three 1-L glass tanks, each holding 5 animals ($\Sigma n = 4 \text{ treatments} \times 3 \text{ tanks} \times 5 \text{ clams} = 60 \text{ clams}$). Water salinity and temperature were kept constant for each treatment and monitored twice daily. Experimental water was renewed daily. No food was provided and a 12-h light:12-h dark cycle was maintained throughout the experiment. In a preliminary study, Lui (2003, unpublished data) observed that *M. meretrix* individuals removed >65% of sand from their body after 72 h in artificial seawater at 20°C and 32‰ (sand remaining [%] = $202.2 \times \exp^{-4.5 \times t} + 34.2$, where t is the duration of sand removal in hours). The clams were, therefore, allowed to depurate over 72 h in the current study, after which all animals were collected for dissection, condition index, and inorganic content measurements.

Dissection of Clams

To study the sand elimination profile and pathway, sand content in three different body compartments, namely the external body fluid, the gut, and the remaining soft body tissues, were determined. The animals in their shells were thoroughly scrubbed with a stiff brush in running tap water, rinsed with distilled water, and left to dry on clean paper towels. Shucking was achieved by inserting a dissecting knife at the site of the adductor muscle. After the shell valves were opened, any liquid was drained and collected in a preweighed aluminum container. This sample was designated

as the external content (EC). The digestive tract was then carefully dissected and designated as the gut content (GC) and placed in a preweighed aluminum container. The remaining body tissues were also placed in another preweighed aluminum container and designated as the body content (BC).

Inorganic Content Analysis and Condition Index

Five empty, preweighed aluminum containers were used as controls for the weighing procedure. All samples, along with the empty shells, were dried in an oven at 80°C for at least 48 h until a constant dry weight was achieved. For each animal, dry weights of all the components (i.e., EC, GC, and BC) and empty shells were weighed using an electronic balance (± 0.00001 g; OHAUS Analytical Plus, Nanikon, Switzerland). Dried samples were then ignited at 500°C in a muffle furnace for 4 h (Takada 1995) and the remaining ash content weighed. Three readings were taken for each sample to ensure a precise mean value for representing the dry ash weight. The inorganic content of each component was calculated as the percentage of the ash weight of the total dry weight of the whole soft-body tissues. Total inorganic content percentage (TIC, %) of each clam was calculated using the following equation:

$$\text{TIC (\%)} = (\text{Total Ash Weight/Total Dry Soft-Body Tissue Weight}) \times 100\% \quad (1)$$

where total ash weight was calculated by summation of the ash weights from all of the three fractions (EC, GC, and BC) and total dry tissue weight was the sum of the dry weights of the gut and body tissues.

The condition index (CI) was calculated using the following equation described in Beninger and Lucas (1984) and expressed as g tissue per g shell weight:

$$\text{CI} = \text{Dry Soft-Body Tissue Weight/Dry Shell Weight} \quad (2)$$

The Rate of Sand Elimination

The rate of sand elimination ($\text{mg g}^{-1} \text{ h}^{-1}$) for each species was calculated using the following equation:

$$\text{Rate} = (\text{TIC}_{\text{final}} - \text{TIC}_{\text{initial}})/\text{Depuration Time} \quad (3)$$

where $\text{TIC}_{\text{final}}$ is the total inorganic concentration (mg g^{-1} dry soft-body weight) at the end of the experiment over the total depuration time, and $\text{TIC}_{\text{initial}}$ is the initial total inorganic concentration (mg g^{-1} dry soft-body weight) at time zero. The results were also expressed as percent sand remaining, which was a ratio of sand content between the control clams (i.e., initial) and each treatment group after 72 h depuration.

Statistical Analysis

Data were tested for homogeneity of variances using Levene's test (SPSS version 10.0). Two-way analysis of variance (ANOVA) was used to test the effect of the treatment (five levels: control and four temperature/salinity regimes) and season (two levels: winter and summer) on the condition index. To compare the inorganic content in each individual components (i.e., EC, GC, and BC) among the control and the four regimes in each season, one-way ANOVAs were used followed by *post hoc* Tukey's multiple comparison tests to identify significantly different means. Finally, a three-way ANOVA was used to test the significance of the effects of temperature (two levels), salinity (two levels), and season (two levels) on the sand removal rate.

RESULTS

Condition Index

As no food was provided during the depuration period, the condition index (CI) of *M. meretrix* decreased significantly after the 72 h depuration for the four treatments in both seasons (Fig. 1; two-way ANOVA: treatment effect, $F_{4, 10} = 35.64$, $P < 0.001$). The CI values were significantly lower in summer than in winter across all of the control and treatment groups (Fig. 1; two-way ANOVA: season effect, $F_{1, 19} = 34.74$, $P < 0.001$).

Inorganic Content in Different Body Compartments

Before depuration, the distribution of sand in the control group of *M. meretrix* followed the order external body fluid (EC) > body tissues (BC) > guts (GC) during the summer (Figs. 2a, 2c, and 2e). In contrast, higher levels of sand grit were found in BC than EC in the control *M. meretrix* group during the winter (Figs. 2b, 2d, and 2f). After the 72-h depuration period, the inorganic content in the gut decreased across all treatments in both seasons, although this decline in the clams exposed to 30‰ and 20°C was not statistically significant (Figs. 2c and 2d). For treatments under high salinity (30‰) regardless of their water temperature and season, the amount of sand depurated was small, and the EC accounted for the largest proportion of overall inorganic content (Figs. 2a and 2b). *Meretrix meretrix* collected in winter and exposed to the two high-salinity regimes showed a significant increase in inorganic content in the EC over the depuration period (Fig. 2b). In terms of total inorganic contents (TIC) per individual clam (Figs. 2g and 2h), the two low-salinity (15‰) treatment groups exhibited significant reductions in their sand contents, whereas the two high-salinity (30‰) treatment groups did not show any significant decline in TIC. These results indicate that the speed of transportation of sand from the body tissues and gut to the external fluid for discharge was much slower in *M. meretrix* exposed to high salinities (30‰) than for the other treatment groups at low salinity (15‰).

The sand removal rate of *M. meretrix* was strongly affected by the different temperature/salinity regimes and season (Figs. 3a and 3b). In general, significantly higher sand removal rates (or lower sand remaining %) were observed at low salinity and low temperature (Fig. 3; Table 1), with the highest elimination rate at 15‰

and 20°C for both seasons (Fig. 3). The rate of sand removal was, however, significantly lower in the summer than in the winter (Fig. 3; Table 1). When comparing the magnitude of the differences among the four groups and the F values (Fig. 3b; Table 1), it was clear that salinity was a more important factor affecting sand elimination rates in *M. meretrix* than temperature and season. This was further supported by the absence of any significant interactions between temperature, salinity, and season on the rate of sand removal (Table 1).

DISCUSSION

Sand Distribution and Depuration

In this study, sand (as determined by inorganic content) was transported and accumulated in different body compartments. Sand particles either passed through the gut and were discharged as feces or pseudofeces or were transported from the tissues to the external body fluid for subsequent disposal from the edge of the shell. During a 72-h depuration period, a considerable amount of sand particles was defecated from the gut by *M. meretrix* in both seasons. The inorganic content remaining in the gut might serve several adaptive functions. First, inorganic matter might contain some essential nutrients that are assimilated through the gut or may have microalgal food items bound to their surface (Huz et al. 2002). Second, Chia (1973) demonstrated that sand grains could be used as a weight belt for juvenile sand dollars, *Dendraster excentricus* (Eschscholtz), that stored these grains in their intestinal diverticulum to help them settle on the sea floor. There is, however, much less information available on the adaptive function of sediment accumulation in burrowing clams.

Salinity Effect

Sand removal rate in *M. meretrix* was higher at low salinities (15‰). A similar result has been reported for the blue mussel, *Mytilus edulis*, and the hard clam, *Mercenaria mercenaria*, concerning the depuration of coliphages and *Escherichia coli* (Richards 1988, Power & Collins 1990). Such an increase in depuration rate may be attributable to an increase in filtration rate and pumping activity at low salinities. Nonetheless, Richards (1988) also reported that other species, such as the soft-shell clam *Mya arenaria* (L.), showed a greater depuration rate at higher salinities (25–30‰), suggesting that the effect of salinity is species-specific. Sobsey and Jaykus (1991) also reported that the range of optimal salinity for effective depuration varies among different bivalve species.

Variation in salinity affects bivalve physiology in a number of ways. Hutchinson and Hawkins (1992) demonstrated that the excretion rate of the oyster *Ostrea edulis* (L.) increased at low salinities, whereas the effect of salinity on their growth varied, depending on the level of food availability. Shell valve activity in response to variation in salinity may be another factor controlling the rate of sand elimination. Akherali and Davenport (1981), for example, showed that the exhalant siphon and valves of the clam *Scrobicularia plana* (de Costa) closed at low salinities and thus prevented their pumping activity.

In the current study, *M. meretrix* removed more sand at low salinities (15‰), suggesting that they perform well under lower salinities. *Meretrix meretrix* occurs on shores in Hong Kong where surface salinities may fall to as little as 2‰ as a result of the summer monsoons and the influx of freshwater from the Pearl

Figure 1. Condition index for *Meretrix meretrix* (mean ± SEM) before and after depuration in artificial seawater at different salinity/temperature regimes for 72 h during summer (open bars) and winter (shaded bars).

Figure 2. Mean (\pm SEM) inorganic contents in (a, b) external body fluid, (c, d) gut, (e, f) body tissues, and (g, h) whole individuals of *Meretrix meretrix* at different salinity/temperature regimes after 72-h depuration period during summer (left column) and winter (right column). Initial values before depuration are shown as shaded bars. Scales for the y-axis vary among the eight figures. In each figure, bars with the same letter are not significantly different (Tukey's multiple comparison test, $P < 0.05$).

River (Morton & Morton 1983). This ability to survive in low salinities is important for infaunal species, as the salinity of estuarine and intertidal zones can fluctuate on an hourly, daily, weekly, and seasonal basis (Gainey & Greenberg 1977, Leung et al. 2002). This may explain why the effect of salinity on sand elimination in *M. meretrix* did not vary between winter and summer.

Temperature Effect

Sand elimination by *M. meretrix* is also temperature-dependent; higher removal rates of sand were generally found at lower temperatures (20°C). Some shellfish sellers in Hong Kong use lower water temperatures to achieve effective sand depuration by clams.

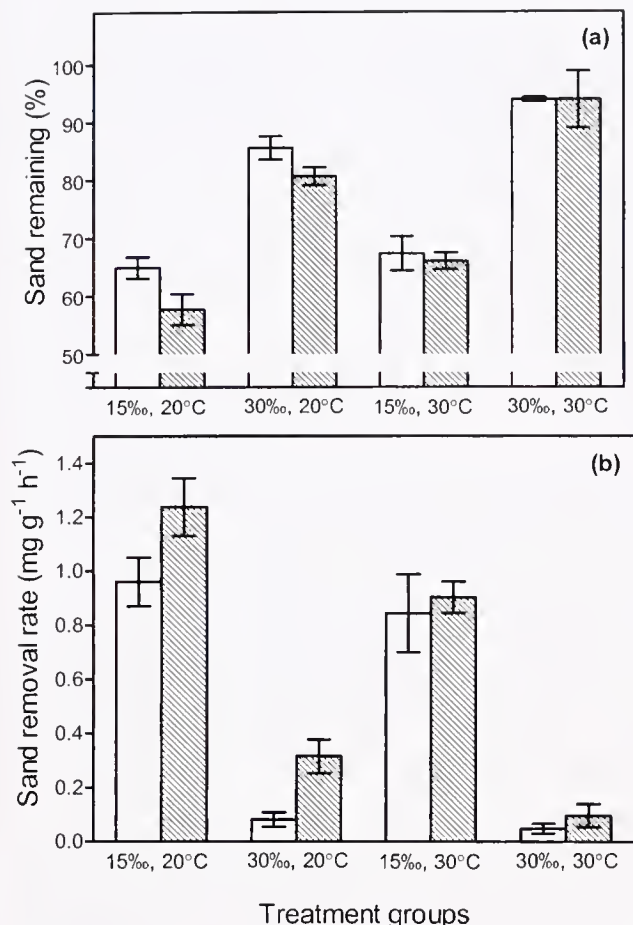

Figure 3. The percentage of (a) sand remaining and (b) depuration rate of *Meretrix meretrix* exposed to different salinity/temperature regimes during summer (open bars) and winter (shaded bars). Mean and SEM are presented.

as survival rates of the shellfish are generally higher at lower temperatures such as 17–18°C (Lui, personal communication). Matthews and McMahon (1999) also demonstrated that the zebra mussel, *Dreissena polymorpha* (Pallas), and the Asian clam, *Corbicula fluminea* (Muller), showed a higher tolerance to hypoxia at lower temperatures. In contrast, however, the West African clam, *Galatea paradoxa* (Born), showed a greater removal of sand at elevated temperatures (Ekanem 2000), whereas the depuration of *E. coli* also increased at higher temperatures in *Mytilus edulis* (Power & Collins 1990) and the king scallop, *Pecten maximus*, (L.) (Heath & Pyke 2001), suggesting that such temperature-dependent responses also vary between species.

Generally, in bivalves, higher water temperatures result in increased feeding rates (in terms of filtration rates; Walne 1972) and higher metabolic rates (in aspects of growth; Robert et al. 1988) and oxygen consumption (Hicks & McMahon 2002). Some workers, however, did not find any significant effects of temperature at the organism level (Denton & Jones 1981, De Vooy 1987, Inza et al. 1998, Blanco et al. 2002), and they argue that the depuration process is independent of metabolic rates, as their target species still efficiently depurated over a broad range of temperatures (6.6–20.5°C). Whether depuration is a temperature-dependent physiologic process in all bivalves species has, therefore, yet to be confirmed.

Combined Effects of Salinity, Temperature, and Season

The effect of temperature on sand elimination by *Meretrix meretrix* was not as pronounced as the effect of salinity. *Meretrix meretrix* must tolerate a wide range of salinities on western shores of Hong Kong. The effect of temperature shock (either hot or cold) is, however, likely to be minimal on the shore because they burrow into the sediment where temperatures are more stable as compared with air temperatures (Yang et al. 2003).

In *M. meretrix*, optimal sand elimination was achieved at low temperatures (20°C) and salinities (15‰) in both summer and winter. Although *M. meretrix* exhibited a higher rate of sand removal in winter than summer, the influence of temperature and salinity was similar between the two seasons. Interestingly, the significantly lower condition indices for *M. meretrix* in the summer (June) were probably associated with low food (i.e., particulate organic matter) availability in the water column (Wong & Cheung 2003), which may possibly be due to heat stress and the increase in freshwater input from rainfall and surface runoff. In contrast, micro- and macroalgae are more abundant during winter in Hong Kong coastal environments (Morton & Morton 1983, Hodgkiss 1984, Nagarkar & Williams 1999) and may considerably enhance the growth of the clams. In such favorable conditions in winter, the clams not only have better physiologic status to efficiently ingest and assimilate nutrients but are also able to excrete waste and depurate sand more effectively. Jovanovich and Marion (1987) also observed a seasonal variation in the depuration of anthracene by the clam *Rangia cuneata* (Sowerby); depuration rates remained low from March to August and rapidly increased to the highest levels during the fall spawning period. This seasonality was related to the reproductive cycle of *R. cuneata* and associated biochemical changes, which in turn affected the physiologic state of the clam.

The oyster *Ostrea edulis* (L.) shows physiologic variation according to seasonality (Hutchinson & Hawkins 1992). A “winter” physiologic state enables *O. edulis* to survive at low temperatures and salinities that are normally encountered during the winter months in its shallow coastal water habitat, whereas a reverse physiologic state was recorded in summer. Similarly, siphonal activity of the soft-shell clam, *Mya arenaria* (L.), was higher during May–September and then strongly declined from October (Thorin 2000). This variation was mainly attributed to seasonal changes in resource availability, water temperature, or individual reproductive state of *M. arenaria*. To our knowledge, the natural reproductive cycle of *M. meretrix* has yet to be established in Hong Kong and South China, although they have been artificially reared or cultured in Southeast Asia. As a result, we are unable to comment on the possible influence of their reproductive cycle on sand elimination.

Conclusions

Sand can be trapped in different body compartments in burrowing bivalves, and this needs to be eliminated for the clam to cleanse itself in the natural environment and for use in the shellfish industry to ensure safety for human consumption. Simple methods for sand elimination using clean seawater or freshwater are currently used by shellfish sellers and seafood restaurant owners worldwide (De Vooy 1987, Carter & Cantelmo 1990, NSSP 1990, Ho & Tam 2000, Heath & Pyke 2001). This pilot study investigated the effect of salinity, temperature, and season on sand elimination in the commercially important clam *Meretrix meretrix*. The rate of sand removal by *M. meretrix* was significantly affected by

salinity and temperature. The highest rate of sand removal was found at low salinities (15‰) and temperatures (20°C). These optimal depuration conditions were identical in both summer and winter, suggesting that lower temperature and lower salinity were physiologically more favorable regardless of seasonality. Depuration rates in the clams were, however, higher in winter for all treatment groups, and this is probably associated with seasonal variation in the climate, food availability, and reproductive cycle of the clam. Further investigation is, however, required to test whether factors other than salinity and temperature, such as repro-

ductive cycle and food availability, could be important in regulating the rate of sand depuration in *M. meretrix*.

ACKNOWLEDGMENTS

The authors thank Cecily Law, Laura Wong, and Lily Ng for their technical support and Cyrus Cheng and Shirley Lui for helping with collecting the samples. Special thanks are also extended to Gray A. Williams, Will Trehwella, Valerie Ho, Justine Tsui, Danny Lau, and Jasmine Ng for their critical reading of earlier drafts of this manuscript.

SURFCLAM HISTOPATHOLOGY SURVEY ALONG THE DELMARVA MORTALITY LINE

YUNGKUL KIM AND ERIC N. POWELL

Haskin Shellfish Research Laboratory, Rutgers University, Port Norris, New Jersey 08349

ABSTRACT The 2002 National Marine Fisheries Service–Northeast Fisheries Science Center (NMFS-NEFSC) survey revealed a substantial reduction in the abundance of surf clams, *Spisula solidissima*, off the Delmarva Peninsula. Increased mortality since 1999 was focused inshore of a southeast trending line extending from approximately the Delaware Bay mouth to the central continental shelf off the mouth of Chesapeake Bay. To investigate further the proximate causes of mortality, we carried out a histopathological survey of surf clams collected along this southeast-trending “mortality” line. The most northern stations had the highest condition indices, the lowest gonadal abnormality scores, with one exception, and the lowest digestive gland atrophy scores. Animals at the stations with lowest average condition index had body weights less than 65% of the average animal taken at the station with the highest condition index. A syndrome describing a malnourished state common in clams taken along the mortality line emerged from this analysis. Animals with low condition were also animals with higher scores of gonadal abnormality and higher scores of digestive gland atrophy. Neither parasites, nematodes and cestodes, occurred commonly, nor instances of hemocyte infiltration, also common, were significantly correlated with low condition index and the associated tissue disorders indicative of malnutrition. Nematodes and the frequently associated instances of focal infiltration by hemocytes were not obviously more common in the southern stations where condition index was low. Cestodes tended to occur more frequently at sites where condition index was low, but infection intensity was high at some stations not so characterized. No disease-causing organisms were observed in this study. Starvation, brought on by regional shifts in temperature mismatching food supply and feeding rate with tissue maintenance needs, offers one potential mechanism explaining the distribution of apparently malnourished clams and the origin of the increase in mortality inshore of the “mortality” line.

KEY WORDS: surfclam, *Spisula*, histopathology

INTRODUCTION

Surf clams, *Spisula solidissima*, support one of the largest fisheries in the Mid-Atlantic Bight and represent a biomass dominant for much of the inner half of the continental shelf of that region (Merrill & Ropes 1969, Weinberg 1998, Weinberg 1999, NEFSC 2003). Prior to 1999, surf clams were abundant from northern Virginia to inshore Long Island, with discontinuous but significant abundances along the southern New England coast and onto Georges bank (Theroux & Wigley 1983, NEFSC 2003). In 1999, estimated stock biomass, just in the Exclusive Economic Zone (EEZ), exceeded 1 million MT (NEFSC 2003), a stock biomass estimated to be at or near carrying capacity throughout much of the surf clam’s range. Surf clams are long-lived, exceeding 30 y in the oldest specimens (Weinberg 1999). Natural mortality rate is estimated to be 0.15 y^{-1} and current fishing mortality rate is less than half this value (NEFSC 2003). Changes in adult abundance thus occur slowly as a consequence of normal population dynamics.

The 2002 National Marine Fisheries Service–Northeast Fisheries Science Center (NMFS-NEFSC) survey revealed a substantial reduction in surf clam abundance off the Delmarva Peninsula (NEFSC 2003). Weinberg (1998) had earlier documented that clams in this region were slower growing than clams from more northern climes. NEFSC (2003) documented that the increased mortality since 1999 was focused inshore of a southeast trending line extending from approximately the Delaware Bay mouth to the central continental shelf off the mouth of Chesapeake Bay. Figure 1 shows the NMFS-NEFSC catches of surf clams during the 2002 survey in this region. No living surf clams were caught inshore of this mortality line, in contrast to the pre-1999 period when surf clams were caught in abundance over much of this area. Since 1999, yearly mortality rate has been well above the stock-wide average of 0.15 y^{-1} previously estimated for this region. The southeastern trend, which follows more or less the isothermic structure of the region, supports the assumption that an underlying causal influence is rising sea temperatures. Weinberg et al. (2002) suggested that increasing temperatures in the Mid-Atlantic Bight

associated with global temperature rise might significantly influence surfclam growth and mortality.

A recent survey of inshore Maryland waters by Powell (2003) reoccupying stations originally sampled by Loesch and Ropes (1977) found few living surf clams inshore of the EEZ along the same stretch of coastline. Although the time when surf clams disappeared from this inshore region is not well-documented, the inshore survey expanded the zone south of Delaware Bay where surf clams, once-abundant, are no longer significant contributors to community biomass. The 2003 inshore New Jersey survey carried out by the New Jersey Department of Environmental Protection documents a substantial decline in the abundance of surf clams inshore of the EEZ off New Jersey as well (NJDEP, personal communication), suggesting that a widespread range contraction along the southern and inshore range boundary of the surf clam may be underway. This boundary probably is determined by temperature, as surf clams do not survive well over the summer in more southern climes (Spruck et al. 1995, O’Beirn et al. 1997) and summer temperature determines faunal boundaries of many species within the Virginian biogeographic province (Cerame-Vivas & Gray 1966).

Surf clams enter high-temperature stress when temperatures exceed 23°C or thereabouts (Loosanoff & Davis 1963, Cable & Landers 1974, Goldberg 1989, Clotteau & Dubé 1993, Walker et al. 1997). Weinberg et al. (2002) observed that bottom water temperatures in the offshore Delmarva region were unlikely to exceed these levels. Thus, a direct effect of temperature as an agent of mortality seems unlikely. However, small increments in temperature above optimal can significantly impact scope for growth in bivalves, a phenomenon often made most manifest in the larger adult animals (Taylor 1960, Hofmann et al. 1994), and temperature-dependent diseases and pathologies are well-known (e.g., Miller & Lawrenz-Miller 1993, Powell et al. 1996, Cook et al. 1998). Either could mediate the influence of temperature as it ultimately modulates the rate of natural mortality. To investigate further the proximate causes of mortality, we carried out a histopathological survey of surf clams collected along the southeast-trending “mortality” line.

Figure 1. August 28, 2003, cruise track of the *F/V Betty C.* Circles of diameter proportional to catch number (see scale) document catches by the NEFSC survey vessel *R/V Delaware II* in 2002 (NEFSC 2002). Stations where no surf clams were caught in the 2002 survey, mostly inshore of the region identified by positive catches in this figure, are not shown. The mortality line runs just west (inshore) of the line established by stations 1, 5, 6, and 9. Squares indicate the seven selected 2002-survey stations reoccupied by the *Betty C.* Two additional stations chosen based on captains' reports are indicated by a ★. Numbers indicate the station numbers assigned to each station for analysis.

METHODS

Sample Collection and Preparation

Samples were collected by the *F/V Betty C.*, homeport Ocean City, Maryland, on August 28, 2003. The cruise track ran the

mortality line from offshore of the Maryland/Virginia border to about the latitude of the mouth of Chesapeake Bay (Fig. 1). A selection of seven of the inshore-most stations at which the 2002 NEFSC survey found living surf clams was resampled. An additional two stations (stations 2 and 3, Figure 1) were sampled based on captains' reports of "sickly-looking" surf clams in commercial catches.

Samples were taken by hydraulic dredge (Wallace & Hoff, in press). Between 10 and 15 animals, catch being sufficient, were selected from each dredge haul for histopathological analysis (Table 1). In all, 105 surf clams were analyzed. The maximum anterior-posterior shell length of each animal was measured. Measured animals were then opened immediately using a stainless steel knife by cutting the adductor muscles. The shucked clam meats were placed in a bucket of seawater, rinsed to remove sand and other hard particles forced into the mantle cavity during capture, drained, and weighed. Immediately after weighing, a 2-cm-thick dorsal-ventral cross-section of tissue including visceral mass, mantle, gill and foot, was removed from each clam using a scalpel. Each section was stored in a glass jar filled with Davidson's fixative for two days until replaced by 70% ethanol for storage (Ellis et al. 1998a).

Tissue Preparation

Methods followed NOAA Status and Trends protocols (Ellis et al. 1998a, Ellis et al. 1998b) except that tissue subsections were excised prior to embedding due to the large size of the clam cross-sections, rather than embedding an entire cross-section. Target tissues included mantle, gill, kidney, gonad, digestive gland, and connective tissue. Tissue samples were embedded in paraffin after dehydration and clearing. The paraffin-embedded tissue blocks were first sliced at 20 μm to expose an entire tissue section. The tissue-paraffin block was then placed in a freezer overnight before final sectioning at 5 μm . Tissue sections were deparaffinized and hydrated using a xylene-ethanol series, stained in a pentachrome series, dehydrated in a series of acetic acid dips followed by acetone, cleared in xylene, and mounted in Permount (Ellis et al. 1998b).

Histopathological Analysis

Tissue sections were examined under the microscope using a 10 \times ocular and a 10 \times objective. When necessary, a 25 \times or 40 \times

TABLE 1.

Average surf clam length, wet meat weight, and condition index, modal gametogenic stage, and the number of females and males analyzed from each station.*

Station	Weight (g)	Length (mm)	Condition (g mm ⁻¹)	Modal Gametogenic Stage	Number Female	Number Male
1	112.8	138.1	0.81	S3,5	7	6
2	77.6	133.1	0.58	S4,5	10	5
3	91.7	137.9	0.66	S3	10	5
4	133.9	154.9	0.86	D4	4	6
5	125.6	143.4	0.87	5	3	7
6	135.0	148.5	0.91	S4,5	5	5
7	103.1	141.7	0.72	D4	6	9

9	69.0	117.0	0.55	S3,S4	2	0

* Modal gametogenic stage is the most common gametogenic stage at the station.

objective was used for closer examination. All parasites and pathologies were scored for intensity based on either a quantitative or semi-quantitative scale. Quantitative scores were used for parasites that could be tallied individually, including prokaryotic inclusion bodies, nematodes, and cestodes. Each nematode cross-section observed was counted, although a single individual may be responsible for a number of tissue cross-sections. Certain tissue pathologies were also quantified by direct counts, including intense localized (focal) or diffuse infiltration of hemocytes.

Some conditions were assigned to semiquantitative scales depending on the intensity or extensiveness of the affected area. These include so-called digestive gland atrophy, characterized by thinning of the digestive tubule epithelium, and abnormal gonadal development, characterized either by unusual development of gametes at the base of the follicles, by an elevated presence of foreign cells and cellular debris in the follicles, or by immature gametes floating free within the follicular lumen. The semiquantitative scales used are defined in Tables 2 and 3.

Discretely counted parasites and pathologies, such as focal and diffuse infiltration of hemocytes, nematodes, and cestodes, were described in terms of their prevalence and infection intensity. Prevalence, the fraction of individuals with the parasite or pathology, was calculated as:

$$\frac{\text{Number clams affected}}{\text{Number clams analyzed}}$$

Infection intensity, the average number of occurrences of a parasite or pathology in the infected individuals only, was calculated as:

$$\frac{\sum_{i=1}^n \text{Number of occurrences of parasite or pathology}}{\text{Number of affected hosts}}$$

Certain statistical procedures, such as principal components analysis (PCA), necessitated combining uninfected and infected individuals by giving the uninfected individuals an infection intensity of 0. The average value, termed weighted prevalence or mean abundance, was calculated as

$$\text{Prevalence} \times \text{infection intensity.}$$

Tissue disorders measured using semiquantitative scales, such

TABLE 2.

Semiquantitative scale used for the evaluation of digestive gland atrophy, adapted from Ellis et al. (1998b).

Score	Description
0	Normal epithelial thickness in most tubules (0% atrophy), lumen nearly occluded, few tubules even slightly atrophied.
1	Average epithelial thickness less than normal, but greater than one-half normal thickness; most tubules showing some atrophy, some tubules still normal.
2	Epithelial thickness averaging about one-half as thick as normal.
3	Epithelial thickness less than one-half of normal; most tubule epithelia significantly atrophied, some epithelia extremely thin (fully atrophied).
4	Epithelium extremely thin (100% atrophied); nearly all tubules affected.

TABLE 3.

Semiquantitative scale used for the evaluation of abnormal gonadal development.

Score	Description
0	Normal gonad.
1	Less than half the follicles are affected.
2	About half the follicles are affected.
3	More than half the follicles are affected.
4	All follicles affected.

as digestive gland atrophy and abnormal gonadal development, were described in terms of the arithmetic mean of their semiquantitative-scale values.

Miscellaneous Analyses

Condition index was calculated as:

$$\frac{\text{Wet meat weight (g)}}{\text{length (mm)}}$$

Gametogenic stage was assigned based on the stages set forth for mussels by Ellis et al. (1998a) (Table 4). These stages can be condensed into the simpler groupings of Ropes (1968). For some statistical analyses, the gametogenic stages were compressed into three larger categories: developing gonad (all D stages, Table 4), fully developed or ripe gonad (stage 5, Table 4), and spawning and partially spent gonad (all S stages, Table 4).

RESULTS

Condition

Condition index was lowest at stations 2, 3, 8, and 9 (Table 1). Average condition index was at or below 0.60 g mm^{-1} for three of these stations, about 34% lower than the station with the highest average, station 6. The most northern group of stations and the most southern station, station 1, had the highest condition indices, averaging above 0.80 g mm^{-1} .

Most surf clams at the northern stations were in a late stage of gonadal development or ready to spawn (Tables 1 and 5). Most surf clams at the southern stations had begun spawning, but few animals had completed spawning. Spent animals were rare (Table 5). These observations generally agree with Ropes (1968) (see also Jones 1981, Chintala & Grassle 1995).

Parasites

Two parasites were common, nematodes and cestodes. Larval cestodes were found in nearly all tissues. Cestodes were reported in *Spisula similis* by Cake (1977), but appear to be undocumented previously in *S. solidissima*. Most cestodes were observed in either the digestive gland, particularly the connective tissue around the gut or attached to the gut epithelium (Plate 1), or in the gonads. A complete accounting of observations by tissue type is: digestive gland (201 observations), gonad (61 observations), mantle (15), kidney (10), blood vessels (10), foot (6), muscle tissue (4), and gill (1). The formation of a thick tissue capsule surrounding the cestode was a frequently observed host reaction. Encapsulated cestodes appeared to be disintegrating and in the process of resorption.

Cestode prevalence fell below 50% only at station 2. Surf clams

TABLE 4.

Stages used to describe the surf clam gametogenic cycle, adapted from Ellis et al. (1998a).

Stage	Description
Resting/spent gonad	
Stage 0	Inactive or undifferentiated.
Developing gonad	
Stage D1	Gametogenesis has begun; no ripe gametes visible.
Stage D2	Ripe gametes present; gonad developed to about one-third of its final size.
Stage D3	Gonad increased in mass to about half the fully ripe condition; each follicle contains, in area, about equal proportions of ripe and developing gametes.
Stage D4	Gametogenesis still progressing; follicles contain mainly ripe gametes.
Ripe gonad	
Stage 5	Gonad fully ripe, early stages of gametogenesis rare; follicles distended with ripe gametes; ova compacted into polygonal configurations; sperm with visible tails.
Spawning gonad	
Stage S4	Active emission has begun; sperm density reduced; ova rounded off as pressure within follicles is reduced.
Stage S3	Gonad about half empty.
Stage S2	Gonadal area reduced; follicles about one-third full of ripe gametes.
Stage S1	Only residual gametes remain; some may be undergoing cytolysis.

infected by cestodes were most common at stations 1, 7, and 9, where prevalence reached or exceeded 85% (Table 6). These are among the most southern stations. Cestode infection intensity was highest at stations 6, 8, and 9. Infection intensity exceeded 6 observations per clam subsection in surf clams taken from these stations (Table 6).

Larval nematodes were observed in nearly all tissues of surf clams in this study: gonad (77 observations, Plate 2), digestive gland (23 observations), the visceral mass between the body wall and the underlying muscle layer (17), foot (8), muscle tissue (2), and gill (1). In some cases, no conspicuous host response was observed. Frequently, however, hemocyte infiltration was observed in association with the worm. Nematodes were found in surf clams collected from all stations (Table 6). Prevalence was highest, exceeding 50%, at stations 1, 7, and 8. Two of these stations are among the three stations in which cestode prevalence was highest. The high prevalence of nematodes in surf clams off the Delmarva Peninsula is anticipated from previous reports. Nematodes were observed to frequently parasitize surf clams by Lichtenfels et al. (1976, 1978) and Perkins et al. (1975). Nematode infection intensity was highest, reaching at least 3 observations per clam subsection, at stations 1, 4, and 5, but exceeded 2 observations per clam subsection at all stations (Table 6). The distribution of nematode infection intensity diverged markedly from that of cestode infection intensity.

A variety of other parasites were found sporadically, including prokaryotic inclusions, often termed rickettsial or chlamydial bodies (Ellis et al. 1998b), also reported to infect surf clams by Otto

et al. (1979), an unidentified worm, and the haplosporidian hyperparasite of larval nematodes, previously reported by Lichtenfels et al. (1978), Payne et al. (1980), Perkins (1979), and Perkins et al. (1975). Prevalence of prokaryotic inclusions was 16%, nearly all cases being located in the digestive tract epithelium. Haplosporidians were observed rarely, hyperparasitizing nematodes in only 4% of the surf clams harboring nematode parasites. One surf clam was observed to have two unidentified worms, one in the mantle and the other in the foot, similar to the echinostomes observed in the gonoducts of Gulf of Mexico oysters by Ellis et al. (1998b) and later identified by Winstead et al. (1998).

Pathologies and Related Conditions

Despite the nomenclatural connotations, neither digestive gland atrophy nor the disorders referred to as abnormal gonadal development are necessarily pathologic. Digestive gland atrophy manifests itself as a thinning of the digestive tubule cells (Ellis et al. 1998b; Table 2). The condition appears to be representative of poor nutrition in some bivalves (e.g., Palmer 1979, Winstead

TABLE 5.

1995), but may result from a variety of environmental stressors (e.g., da Ros et al. 1998, Axiak et al. 1988, Marigómez et al. 1990, Gold-Bouchot et al. 1995), although many of these likely also affect nutrition. Winstead (1995), for example, found that poor nutrition was a key element in producing the condition in oysters and that the digestive gland recovered to its normal state relatively rapidly once food supply improved. Therefore, digestive gland atrophy is not necessarily a pathology.

The origin of digestive gland atrophy in surf clams is unknown. Digestive gland atrophy was highest at the more southerly stations (Table 6). Averages at stations 1–3 and 8–9 were above 2 on a 0–4-point scale (Plate 3).

Putative cases of abnormal gonadal development was observed in some surf clams. This set of disorders was characterized by one or more of three conditions. In some cases, gametes developed in an unusual way at the base of the follicles. Follicles sometimes were filled with degenerating gametes and cellular debris beyond the extent normally observed at the end of the spawning cycle (Plate 4, left; Plate 5). Occasionally, immature eggs were observed floating free in the lumen of the follicle (Plate 4, right). The approach used to score instances of abnormal gonadal development was to estimate the fraction of follicles affected, not the degree of effect in each follicle (Table 3). Normally, the entire follicle was completely affected or unaffected. Putative gonadal abnormalities were observed at all stages of the gametogenic cycle (Table 5), so that the possibility that these disorders represent normal phases of gametogenic development seems low. Nevertheless, the origin of the gonadal abnormalities summarized in Table 6 is unknown, as are their statuses as normal or pathologic conditions. Cases of abnormal gonadal development were most common at stations 3, 7, and 8 (Table 6).

Cases of hemocytic infiltration may be focal (localized) (Plate 6) or diffuse (extensive). The type of affected tissue and type of irritation responsible influence the nature of the cellular response (Ford & Tripp 1996). Diffuse infiltration of hemocytes is differentiated from focal infiltration when the affected area does not appear to have a clear center or focal point of highest hemocyte concentration and hemocytes are abundant and distributed broadly over a large section of tissue (Ellis et al. 1998b). In this study, instances of hemocytic infiltration were observed mostly in the connective tissues.

TABLE 6.

Prevalence and infection intensity of the common parasites, pathologies, and tissue disorders observed.*

Station	Nematode Prevalence	Nematode Intensity	Cestode Prevalence	Cestode Intensity	Focal Hemocytic Infiltration Prevalence	Focal Hemocytic Infiltration Intensity	Diffuse Hemocytic Infiltration Intensity	Diffuse Hemocytic Infiltration Intensity	Digestive Gland Atrophy	Abnormal Gonadal Development

*The tissue disorders denoted as digestive gland atrophy and abnormal gonadal development are shown as the mean of their semiquantitative scale values. Calculation of prevalence and infection intensity for the parasites and pathologies is described in the "Materials and Methods" section.

Plate 3. Digestive gland atrophy in a surf clam, scored a 3 on the 0–4-point scale (Table 2). Note the mixture of atrophied tubules extending from the top to the bottom of the plate along the center line and the more normal tubules on the lower right characterized by star-shaped lumens. Scale bar is 100 μ m.

Animals with observed cases of focal hemocytic infiltration were most common at stations 1, 5, and 8 (Table 6); prevalences reached or exceeded 90% at these stations. In contrast, the frequency of focal hemocytic infiltration was highest at stations 1, 7,

and 9, where intensity averaged near or above 2.5 observations per clam tissue subsection. These stations had highest prevalences of nematodes and subsequent statistical analyses support the belief that the two, nematodes and focal infiltration of hemocytes (Plate 6), often are associated. Prevalence of diffuse hemocytic infiltration was highest at stations 1, 7, and 9 (Table 6), where prevalence reached or exceeded 50%. Frequency of occurrence in individual clams, however, was highest at stations 2, 3, and 7. The occurrence of diffuse hemocytic infiltration was not obviously associated with either of the common parasites, nematodes or cestodes.

Association of Parasites, Pathologies, and Other Indicators of Health

We assumed that condition index was a good overall indicator of animal health and examined the relationship between condition index and the common parasites, pathologies and other tissue disorders. We focused on infection intensity, rather than prevalence. Condition index is the ratio of wet weight to length. However, this ratio is not constant over all size classes. Typically, the shell growth form changes with age, such that shell width increases disproportionately with shell length. As a consequence, larger clams typically have a disproportionately larger weight per centimeter of length, and, accordingly, condition index tends to average higher. Preliminary analyses confirmed that some histopathological variables were better explained by shell length than by weight or condition, as a consequence of the dichotomous nature of length. For this reason, we first used principal components analysis

Plate 4. Putative gonadal abnormalities in female surf clams. Upper left: A section through an S3-stage gonad (Table 4) showing degenerating eggs and cellular debris among unspawned, fully mature eggs. Upper right: A section through an S3-stage gonad (Table 4) showing immature eggs floating free in a follicle with mature eggs (note the follicles in the center of the field). Lower: A section through a normal S3-stage gonad. Scale bar is 100 μ m.

(PCA) to separate the simple relationship between weight and length, encompassed in the measure of condition, from the additional effect of length, presumably reflecting the change in allometric growth form. This PCA provided two significant factors. Factor 1, hereafter referred to as the condition factor, combined the simple measurement of weight with condition index. The variable length was split, as anticipated, relatively evenly between factors 1 and 2, the latter hereafter referred to as the additional length factor.

We also used PCA analysis to generate variables describing the relationships of the various parasites, pathologies, and other tissue disorders because preliminary analyses indicated that many pairwise correlations were significant (Spearman's rank correlation, $\alpha = 0.05$). Three PCA factors were significant. Factor 1, hereafter referred to as the nematode factor, combined the variables of nematode infection intensity and the frequency of focal hemocytic infiltration, thereby supporting a relationship between this parasite-tissue pathology pair. Factor 2, hereafter referred to as the abnormality factor, was principally determined by the mean intensity of gonadal abnormality scores. Cestode infection intensity loaded about evenly between these first two factors, probably because cestode prevalence and cestode infection intensity tended to be somewhat differentially distributed (Table 6). Factor 3, hereaf-

ter referred to as the atrophy factor, was primarily determined by the degree of digestive gland atrophy. Diffuse hemocytic infiltration did not contribute significantly to any of these three PCA factors.

ANOVAs were run using the condition and length factor scores as dependent variables, the nematode, abnormality, and atrophy factor scores as independent variables, and using sex and gametogenic stage compressed into the three categories of developing gonad, ripe gonad, and spawning or partially spent gonad as added main effects. The condition factor was significantly influenced by the abnormality factor ($P = 0.0038$). Low condition indices were associated with high levels of abnormal gonadal development (Fig. 2). Cestode infection intensity also loaded on this factor, and the highest cestode infection intensities were associated with a small reduction in condition index (Fig. 2), however, not to the extent observed for gonadal abnormalities (Fig. 2).

The length factor described that part of the variation in length not encompassed by the simple relationship of weight and length as expressed by condition. The length factor was significantly influenced by the degree of digestive gland atrophy, as expressed by the atrophy factor scores ($P = 0.015$). Highest digestive gland atrophy scores occurred in the smallest animals (Fig. 3). The same trend was present with condition index (Fig. 3), but this trend was not statistically significant when analyzed by comparison of the appropriate PCA scores. The main effects of sex and gametogenic stage were not significant.

The nematode factor, representing nematode infection intensity and the frequency of focal hemocytic infiltration, and partially explaining cestode infection intensity, did not significantly influence either the condition or the length factor (Fig. 4), nor were the main effects of sex or gametogenic stage significant.

We reserved the analysis, taking the nematode, abnormality, and atrophy factors as dependent variables and the length and condition factors as independent variables to determine the degree to which condition, length, gametogenic stage, or sex influenced the occurrence of parasites and pathologies. Sex and compressed gametogenic stage were again included as main effects. Not surprisingly, the atrophy factor as a dependent variable and the length factor as an independent variable were significantly related ($P = 0.0074$). The intensity of digestive gland atrophy varied with clam length (Fig. 3). The atrophy factor was not significantly influenced by sex nor, as might be expected, was it significantly influenced by gametogenic stage, or the condition factor. The abnormality factor,

that expressed the severity of gonadal abnormality and, to a certain extent, cestode infection intensity, was significantly influenced by the condition factor ($P = 0.0034$). Higher gonadal abnormality scores occurred in animals with lower condition index (Fig. 2). Gametogenic stage also significantly influenced the abnormality factor scores ($P = 0.02$). An *a posteriori* LS means test revealed that gonadal abnormalities, as expressed by the factor scores, were more severe within gametogenic stages in which evidence of spawning was present (S stages, Table 4) than with stages of gamete development (D stages, Table 4) ($P = 0.03$) or ripe gonads without evidence of spawning (stage 5, Table 4) ($P = 0.0074$). Animals rated as ready to spawn had lower gonadal abnormality scores than those in which some evidence of the initiation of spawning was present (Fig. 5). Cestode infection intensity varied little with gametogenic stage (Fig. 5), indicating that the primary effect determining the relationship between the abnormality factor and gametogenic stage was the degree of gonadal abnormality.

Factor one, jointly describing nematode infection intensity and

the frequency of focal hemocytic infiltration, plus some portion of cestode infection intensity, was significantly influenced only by sex. Nematode factor scores were higher in males than in females ($P = 0.043$), as were nematode infection intensities (Fig. 6). The frequency of focal infiltration of hemocytes was also elevated, although to a lesser degree in males (Fig. 6).

DISCUSSION

We investigated the health of surf clams taken along the "mortality" line running southeast off the Delmarva Peninsula that separates stations that yielded no living surf clams in the 2002 NMFS survey (NEFSC 2003) from those where living surf clams were collected. Condition index may serve as a good overall indicator of animal health, once gametogenesis is taken into account, as condition normally varies with the gametogenic cycle (Beninger & Lucas 1984, Choi et al. 1993, Choi et al. 1994, Loesch & Evans 1994). Condition declines for many reasons, including low nutri-

tion produced by restricted food supply (Engle & Chapman 1953, Deslous-Paoli & Héral 1988, Bielefeld 1991, Rheault & Rice 1996, Honkoop & Beukema 1997, Smith et al. 2000, Krauter et al. 2003) and by the influence of parasites and disease (Plana et al. 1996, Pérez Camacho et al. 1997, Olivas-Valdez & Cáceres-Martínez 2002, Hine 2002).

The most northern stations, 4, 5, and 6, had the highest condition indices, the lowest gonadal abnormality scores, with one exception, and the lowest digestive gland atrophy scores. Animals at the stations with lowest average condition index had body weights less than 65% of the mean animal taken at station 6 with the highest condition index. We assume, from Weinberg et al. (2002), that surf clams at station 6 already averaged lower in condition index than clams from more northern climes, as condition index is normally lowest off the Delmarva Peninsula. The condition indices we recorded from clams at the southernmost stations occupied in this study were extremely low in comparison to values recorded by Loesch and Evans (1994) for the nadir of the normal seasonal cycle. Loesch and Evans (1994) recorded a drop in condition index of 20–25% in the late fall from summertime highs. Though exceptions exist (e.g., Héral & Deslous-Paoli 1983, Garton & Haag, 1993), most bivalves lose about 20–25% of their body weight upon spawning (Browne & Russell-Hunter 1978, Powell & Stanton 1985, Choi et al. 1994, DiBacco et al. 1995), so the observations of Loesch and Evans (1994) are typical of bivalves.

Larger reductions in condition index in bivalves, of the order observed at the more southern stations in this study, are often related to nutritional challenge. Pérez Camacho et al. (1997), for example, record an approximately 50% decline in condition in parasitized *Mytilus edulis*. Beninger and Lucas (1984) record reductions in excess of 50% in *Tapes* clams during periods of reduced food supply, particularly over winter. Similar results are reported by Honkoop and Beukema (1997), Olivas-Valdez and

Cáceres-Martínez (2002), Barber et al. (1988), and others. Although a number of experiments subjected bivalves to long-term deprivation of food (e.g., Holland & Spencer 1973, Riley 1976, Riley 1980, Hawkins et al. 1985, Bielefeld 1991, Chase & McMahon 1994, Hummel et al. 1995), all of which show decreases in condition or body components related to condition, the degree to which bivalves can recover from a 30% to 50% loss of somatic tissue is poorly known. Leighton and Boolootian (1963) recorded one of the few measures of mortality due to starvation. They report that abalone began to die after a weight loss of 12–24% over a two- to three-month time period. Nevertheless, condition indices much below 30% of normal, as observed in this study at the southernmost stations, particularly during the summer months when condition should be at or above the long-term mean value (Loesch & Evans 1994), strongly imply that malnourished clams were common along the “mortality” line.

Additional evidence of malnutrition accrues from the tendency for stations yielding clams in lowest condition to also yield clams with above normal scores for abnormal gonadal development. In studies of the surf clam gametogenic cycle, neither Ropes (1968), Jones (1981), nor Chintala and Grassle (1995) figure gonadal conditions of this type. Although the origin of the gonadal abnormalities observed in these clams is unknown, as is the accuracy of their designation as abnormal, an unusual degree of gonadal resorption or loss of gonadal integrity does seem a likely cause. Gonadal resorption often occurs at the end of the gametogenic cycle (e.g., Ropes 1968, Griffiths 1977, Chung & Kim 1994, Ellis et al. 1998a), but resorption is also a frequent indicator of malnutrition (Riley 1976, Bielefeld 1991, Hofmann et al. 1992, Barber 1996, Delgado & Pérez Camacho 2003). The correlation between low condition index and higher degrees of gonadal abnormality in this study suggests that the latter originates in the same causative factors that produce the unusually low condition indices.

Digestive gland atrophy also is normally associated with factors compromising nutritional status. In this study, highest scores of digestive gland atrophy tended to occur in smaller animals (Spearman’s rank correlation, $P = 0.0045$). Smaller animals were collected at the more southern stations and these stations also were characterized by low condition index. Why digestive gland atrophy should be more significantly influenced by the additional length factor rather than the factor encompassing weight and condition is unknown.

A syndrome would appear to emerge from this data analysis. Animals with low condition are often animals with higher scores of gonadal abnormality and higher scores of digestive gland atrophy. Among the factors often associated with reduced condition, as well as impacting gonadal development (e.g., Powell et al. 1999, Arnold et al. 2002, Park et al. 2003), is parasitism and disease. Two parasites were commonly observed in the surf clams: nematodes and cestodes. Parasites of this type are rarely associated with overt pathologies, beyond the frequently observed inflammatory response characterized by focal hemocytic infiltration. Infection intensities were routinely higher than recorded in mussels and oysters from the east coast, however (Kim et al. 1998). Two pathologies were also recognized, focal and diffuse hemocytic infiltration. One, focal infiltration of hemocytes, would appear to be related to the presence of worms, particularly parasitic nematodes.

Neither of the two parasites nor either of the pathologies, however, was significantly correlated with condition index or length, as expressed by comparisons between the appropriate PCA factor scores, save for the influence of cestode infection intensity in the

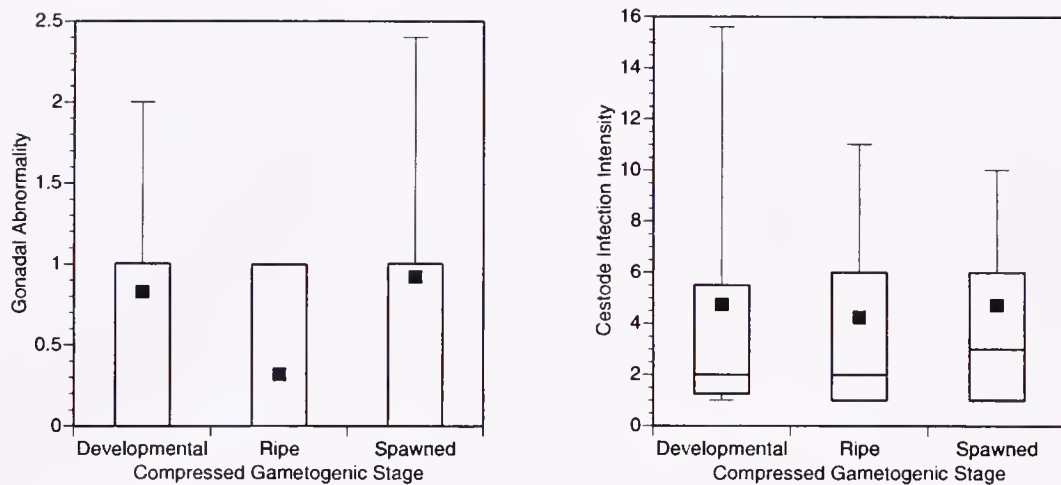

Figure 5. Left: Box plot relating the severity of gonadal abnormality (scores defined in Table 3) to gametogenic stage (defined in Table 4) in surf clams. Right: Box plot relating cestode infection intensity expressed as the number of observations per clam subsection to gametogenic stage (defined in Table 4) in surf clams. The box encompasses the 25th and 75th percentiles with the median as the dividing line. The whiskers identify the 10th and 90th percentiles. The mean is indicated by a ■. For the gametogenic stages designated "Spawned" and "Developmental" on the left graph, and median and 75th percentile are equivalent; for the gametogenic stage designated "Ripe," the median and 25th percentile are equivalent, as are the 75th and 90th percentiles.

PCA factor principally describing the occurrence of gonadal abnormality. By comparison, the PCA factors representing the disorders denoted as gonadal abnormality and digestive gland atrophy significantly influenced one or both of the condition and length factors. Nematodes and the frequently associated cases of focal hemocytic infiltration were not obviously more common in the southern stations where condition index was low. Cestodes tended to be more common at sites where condition index was low, but not consistently so. Infection intensity was high at station 6, for example, where the highest condition index was also recorded. One cannot fully exclude disease as an underlying cause of the malnourished state, however, although no disease-causing organisms were observed in this study. Many disease-causing organisms are readily identified, but cases that are otherwise, such as the withering syndrome of abalones in which the etiological agent was not easily confirmed (VanBlaricom et al. 1993, Friedman et al.

1993, Moore et al. 2001, Moore et al. 2002), are well-known. Nevertheless, parasites and disease do not seem to be likely mediators of the syndrome that appears to evince a malnourished state observed in surf clams along the mortality line.

Sex and gametogenic stage also offered little explanatory information. Sex was unrelated to any condition save possibly the presence of nematodes. Gonadal abnormalities were more common in clams with gonads that showed evidence of the initiation of spawning, suggesting that abnormal development may become more likely or more recognizable as the gametogenic cycle progresses. Digestive gland atrophy and condition index were not so associated. Many bivalves, even when malnourished, attempt to complete gametogenesis (e.g., Riley 1976, Bielefeld 1991, Delgado & Pérez Camacho 2003), though not necessarily successfully, and surf clams seem to be no exception, based on the limited information presented here.

Figure 6. Box plot relating nematode infection intensity expressed as the number of observations per clam subsection on the left and the frequency of focal hemocytic infiltration per clam subsection on the right to sex in surf clams. The box encompasses the 25th and 75th percentiles with the median as the dividing line. The whiskers identify the 10th and 90th percentiles. The mean is indicated by a ■.

Ready alternatives as causative factors producing a malnourished state do exist, however. A rise in temperature can restrict scope for growth, particularly in the temperature range above optimal where respiratory rate continues to increase, but filtration rate begins to decline (Ali 1970, Newell et al. 1977, Winter 1978, Newell & Branch 1980, Brock & Kofoed 1987). Variations in climate and oceanographic conditions might also directly influence food supply (e.g., Lehman 2000). The combination of rising temperature and reduced food for such large animals as surf clams requiring substantial food resources to maintain their bulk could be lethal (Taylor 1960, Powell et al. 1995). Unfortunately, sufficient information is not available to investigate further the origin of the malnutrition observed. The evidence does suggest, however, that the regional mortality event observed by NEFSC (2003) in 2002 may be continuing, that animals in nutritionally limiting situations continue to exist over a wide area off the Delmarva Peninsula, and that many of these animals are in sufficiently poor condition that recovery is not necessarily assured, should the environmental conditions leading to malnourishment relax.

The evidence suggests, therefore, that factors compromising scope for growth, either a direct reduction in food, factors reducing the ability to acquire food, or factors increasing the energy requirements of maintenance, offer potential as the underlying cause of malnutrition. Range shifts are often determined by extreme events,

particularly along the trailing edge (e.g., Taylor 1934, Kennedy 1990). Range expansion occurs by recruitment. Range contractions in short-lived animals can occur by the failure thereof. For long-lived animals, such as surf clams, rapid contractions in range require increased adult mortality along the trailing boundary and such contractions may occur more rapidly than the expansion along the leading edge (Kennedy 1990). Starvation brought on by environmental shifts mismatching food supply and feeding rate with the energy demands of tissue maintenance offers one potential way this might occur. The malnourishment syndrome identified here, low condition index associated with increased frequency of gonadal abnormality and increased levels of digestive gland atrophy, may evidence such a process.

ACKNOWLEDGMENTS

The authors thank the captain and crew of the *F/V Betty C.* for help in sample collection and J.H. Miles & Co., Inc., for providing the vessel. We appreciate the help of J. Weinberg in providing station locations and catch statistics from the 2002 NMFS-NEFSC survey. This research was supported by the National Fisheries Institute Clam Committee and the North American Clam Association. We appreciate the support and logistical help from both chairmen, Dave Wallace (NACA) and Daniel Cohen (NFI-CC).

REPRODUCTIVE CYCLE OF THE STOUT RAZOR CLAM, *TAGELUS PLEBEIUS* (LIGHTFOOT, 1786), IN THE MAR CHIQUITA COASTAL LAGOON, ARGENTINA

M. CLEDÓN,^{1,2,*} A. C. PERALTA BRICHTOVA,³ J. L. GUTIÉRREZ⁴ AND P. E. PENCHASZADEH¹

⁴Universidad de Mar del Plata, Argentina

ABSTRACT A population of the dioecious euryhaline bivalve, *Tagelus plebeius*, living in the Mar Chiquita Lagoon (37°40'S, 57°26'W) exhibits an annual gonad cycle. Spawning occurs during the austral spring and summer (October to March) and is dependent on water temperature. Two reproductive modes were observed during consecutive years: partial spawning events in December 1999 to January 2000 and at the end of March 2000, and one continuous spawning event in October 2000 to March 2001. Mature oocytes measured 75–95 μ m. At the end of the spawning events there was a sharp drop in body weight, indicating that body mass is determined by gonad status.

KEY WORDS: razor clam, reproduction, *Tagelus*

INTRODUCTION

The Psammobiid euryhaline bivalve *Tagelus plebeius* (Lightfoot 1786) inhabits tidal flats on the Atlantic coast of the Americas (Osorio Ruiz 2002) from 34°N to 41°S, contributing more to the total biomass of these areas than any other bivalve. It is such a common inhabitant of the estuaries and coastal lagoons of Argentina, that shell beds of this species modify the environment (Gutiérrez & Iribarne 1999). Individuals live buried in sandy substrates, and can tolerate a wide range of salinities (<10‰ to >30‰) and temperatures (Chanley & Castagna 1971).

Most *Tagelus* species, including *T. plebeius*, are economically important as a source of food in Chile, China, Spain, and other countries, with the harvest of more than 4000 tons per year in Chile alone (Osorio Ruiz 2002). Some information is available on the biology of other *Tagelus* species such as, *T. dombeii* (Urban 1996) and *T. divisus* (Fraser 1967). Blommer (1907) described the anatomy of *T. gibbus* and *T. divisus*, and *T. dombeii* has been used as an indicator of contamination in marine environments (De Gregori et al. 1994). Despite its economic importance, there are some large gaps in our knowledge of the biology of *T. plebeius*. Here we present a study of the reproductive cycle of a population in Mar Chiquita Lagoon (Buenos Aires, Argentina).

MATERIAL AND METHODS

From September 1999 to August 2001, 20 adult *T. plebeius* (more than 40 mm in shell length) were collected every month with a shovel. The sampled population is located in the middle zone of the Mar Chiquita Lagoon. The maximum length of each specimen was measured to the nearest mm with a digital vernier calliper. The edible part was removed from the shell, weighed to the nearest mg, fixed in Bouin's solution for 72 h, preserved in 70% alcohol, dehydrated in ethanol series and infiltrated with paraffin. For histologic analysis, gonad sections of 5 μ m thickness were stained with Mayer's hematoxyline and eosin. About 10 females of each sampled month were analyzed under a Zeiss microscope. Of each female the diameter of 10 unbroken oocytes, showing nucleoli were measured from 5 sections. These sections were

anatomically distant from each other to avoid repetition of measurements.

Surface water temperature was measured with a mercury bulb thermometer four times a day on 3 consecutive days of each month to calculate the daily mean temperature of the month. The mean water temperature and its standard deviation (SD) were plotted together with the gonadic stage and wet weight of the individuals.

RESULTS

No Hermaphroditism or Sex Reversal Was Encountered

Sex can be distinguished only histologically and presents a ratio of male to female not significantly different from 1:1 ($\chi^2 = 0.52$, $P > 0.05$).

The diameter of the oocytes (Fig. 1) and mean body mass (Fig. 2) were correlated with water temperature (Fig. 3), with significant decreases at the beginning of spawning and reabsorption from October 1999 to January 2000 (ANOVA, $P < 0.05$), May to July 2000 (ANOVA, $P < 0.05$) and November 2000 to March 2001 (ANOVA, $P < 0.05$).

No Asynchronous Gametogenesis Was Observed

Figure 1 shows how mean oocyte diameter increases, whereas the SD remains more or less constant, during winter maturation. Before spawning begins, all oocytes are mature, mean oocyte diameter is at its highest with a small SD. Once spawning begins, the mean oocyte diameter decreases and the SD increases, because a new cohort of oocytes simultaneously starts to grow. As water temperature rises in the early spring, body mass increases and gametes start developing (Fig. 4), reaching their maturity (Fig. 5) in October. During 1999, the main reproductive event occurred between December and January, when modal oocyte diameters were 75–95 μ m and water temperature in the lagoon was about 20°C. This event was characterized by a nearly complete evacuation of the gonads (Fig. 6) and a sharp drop in shell free wet mass (SFWM) to the annual minimum. After this event, new gametes developed and body mass increased again rapidly. Another spawning event occurred at the end of March 2000 with a similar body mass fluctuation.

During the period of sexual activity, non-released gametes co-exist with developing ones. When the water temperature dropped

Figure 1. Mean oocyte diameter, and standard deviation, of *Tagelus plebeius* from Mar Chiquita Lagoon. The data gap in June to July 2000 and May to August 2001 is due to the ovary reabsorption phase showing now measurable oocytes. $n = 1826$.

below 20°C, gonad reabsorption started (Fig. 7) and SFWM decreased. By winter, gonads were completely reabsorbed.

During the year 2000, the population showed a different reproductive strategy, characterized by a progressive spawning event that lasted the entire summer, from October 2000 to March 2001. The modal diameter of oocytes during December 1999 was approximately 50 µm because of a lack of small oocytes, and 70 µm in December 2000.

DISCUSSION

We observed two different spawning modes in *T. plebeius*. The gonads can either be emptied completely in a single event, or oocytes can be retained for later release during various partial-spawning events throughout the summer.

After a complete spawn, gonad recovery was immediate, allowing a second spawning event during March. A similar pattern has been observed in a population of *Donax trunculus*, along the coast of Portugal, with one major spawning event at the beginning of spring and the other lasting the whole summer (Gaspar et al. 1999). Tirado & Salas (1998) reported two peaks of gametes release in *D. trunculus*, in May and August (septentrional summer). Our study also agrees with the report of Chanley and Castagna (1971) on *T. plebeius*, where they reported individuals spawning in laboratory at the end of the winter and again mature gametes in

Figure 2. Seasonal variation in shell free wet mass (SFWM) of 50–60 mm of *Tagelus plebeius* from Mar Chiquita Lagoon. $n = 480$.

Figure 3. Mean water temperature and Standard Deviation in Mar Chiquita Lagoon.

summer. Another case of partial spawning events was observed in a population of *Tellina petitiiana* in Golfo Nuevo, Argentina (Baron & Ciocco, 2001). First partial spawning was registered in November (late spring) and from December to February most of the clams were in the partial evacuation and recuperation stages. This spawning strategy coincides with the data presented here for *T. plebeius*.

Dekker & Beukema (1999) reported a fluctuation in the reproductive success of populations of *Tellina tenuis* and *Abra tenuis* in the north of their geographical range, depending on summer and winter water temperatures. This can also occur in *T. plebeius*, where temperature can influence the start of gametes development and spawning. Variation in environmental conditions cannot only produce inter-annual changes in a population's reproductive strategy, as we report here, but also in the same year among populations. Tirado & Salas (1998) reported reproduction of *D. trunculus* from February to October in a Spanish Mediterranean population, whereas Gaspar et al. (1999) reported reproduction from March to August in a Portuguese population at the same latitude. If the population does not change its strategy, its recruitment success

Figure 4. *Tagelus plebeius* developing female and male gonads. Developing oocytes (do) in female gonad. Scale bar: 100 µm. *Tagelus plebeius*. Developing spermatides (sp) in male follicles. Scale bar: 500 µm.

Figure 5. Completely developed female and male gonads in *Tagelus plebeius*. Mature oocytes (mo). Scale bar: 400 μ m.

could be affected, as reported for *T. tenuis* in Dublin bay by Wilson (1997). This shifting effect is more evident when comparing populations from different latitudes where a more continued and less marked reproductive season near the Equator contrasts with biannual cycles in higher latitude populations. This phenomenon is registered for many species and probably it occurs in other *T. plebeius* populations.

So, in these cases temperature dependency can explain the changes in reproductive strategy as suggested by Dekker & Beukema (1999).

Piccolo & Perillo (1997) reported water temperature in Mar Chiquita between 9 °C and 25°C for the period 1994 to 1995. This is a moderated fluctuation compared with the 4.5°C to 27°C registered in the present work. These differences surely influence the reproduction of this population. In this sense it would be necessary to study how the population dynamics change under different environmental conditions.

Salinity was not registered in our study; however, there is a longitudinal gradient between the mouth of the lagoon (34‰), the middle zone (22‰), and the streams entrances (3‰ to 4‰) with a very homogeneous vertical distribution (Piccolo & Perillo 1997). Because we have no available data on salinity, we inferred a more or less constant salinity of 22‰ in the sampled area.

T. plebeius is the only present bivalve in this community. The recruitment of this population has not been studied here, but it

Figure 6. Partially spawned female gonad in *Tagelus plebeius* with some empty areas (ea), mature oocytes (mo) and new developing oocytes (no). Scale bar: 500 μ m.

Figure 7. *Tagelus plebeius* female gonad after spawning presenting conspicuous empty spaces (e) and a less compressed gonadic anatomy. Scale bar: 600 μ m.

could be only influenced by the population density, as reported by Stephen (1938) for *T. tenuis*, where it attains high population densities in spite of sporadic recruitment, coincides with high environmental temperatures, and probably an overall improvement in conditions.

The seasonal weight changes of *T. plebeius* individuals correspond with their reproductive cycle. This observation can be also related to the fact that euryhaline bivalve species commonly show a pattern of two spawning peaks per reproductive season, as reported for *Abra alba* (Hily & Le Bris 1984). A body mass cycle governed by the gonad cycle has been observed in other commercial species of the genus, as *T. dombeii* (Urban 1996) and *T. divinus* (Fraser 1967). Urrutia et al. (2001) reported high lipid content in a Chilean *T. dombeii* population during October and February, at the time when gonad weight is higher, this could explain the increment in body mass when spawning approaches.

Tagelus plebeius is a good candidate for managed exploitation or aquaculture for the following reasons: because other *Tagelus* species are commercialized (Urban 1996 Osorio Ruiz 2002) its similarity to the other commercial species ensures its insertion in an existing market.

The stock can be managed quite easily because they inhabit coastal lagoons that can be more easily monitored and protected in comparison with open waters species. Moreover, the coast of the province of Buenos Aires is formed by a stable paleodunes field (Codignotto & Aguirre 1993) where artificial coastal ponds could be constructed for its farming at low cost.

Animals of Marketable Quality May Be Obtained Over Several Months

Studies on the populations growth rate, size at sexual maturity, and evaluation of the stock have to be carried out, as well as the influence of environmental changes on the populations dynamics, to complete the knowledge on this species before starting its commercial exploitation.

II, C1428EHA, Buenos Aires, Argentina.

ABSTRACT To study the process of regeneration and its effect on the morphology of the inhalant siphon of a tellineacean bivalve, *Donax denticulatus*, individuals were artificially amputated and placed in aquaria under laboratory conditions, in the absence of predators. After amputation, two individuals were sacrificed twice a day (9 AM and 5 PM) during a 9- day period, and their siphons were examined in the microscope. Within the first 24 hours after amputation, the process was slow, and only the rudiments of the primary tentacles were visible. However, between the second and the third day a fast transformation of the siphon was observed, with regeneration of secondary and tertiary tentacles. The siphon was fully regenerated on the fifth day after amputation. One month later, the siphon showed the same aspect than at the fifth day. Despite the delay observed in the regeneration of the siphon within the first 24 hours after amputation, probably due to physiologic constraints associated with the lack of well developed tentacles, regeneration showed to be a fast process. Development of primary and secondary tentacles must therefore play an important role in providing basic functionality to the siphon, as well as to the whole organism.

KEY WORDS: siphon, regeneration, *Donax denticulatus*, tellineacean bivalve, fish cropping

INTRODUCTION

To maintain their basic physiologic functions (i.e., feeding, defecation, and gas exchange), infaunal organisms must establish contact with the sediment-water interface. Soft bodied species often achieve this interaction by exposing parts of their bodies outside the sediment in the form of specialize structures such as ramified tentacles (e.g., polychaetes) or siphons (e.g., bivalves) that maximize the area of contact with the water column, thus optimizing the interaction with environment (McLachlan et al. 1995). However, the exposure of such structures can enhance the risk for predation, making infaunal organisms more vulnerable to tissue browsing by benthic feeders such as, crab and shrimp (Kamermans & Huitema 1994), pelagic juvenile flatfish (Trevallion et al. 1970), and birds (Zwarts 1986). Siphon cropping has been reported for several bivalve species (Trevallion 1971, Hodgson 1982, Peterson & Quammen 1982, Zwarts 1986). After amputation, siphons can regenerate providing a renewable source of secondary production that has been shown to maintain higher trophic levels (Penchaszadeh 1983, Pekkarinen 1984, Riera 1995, Luzzatto & Penchaszadeh 2001). However regeneration occurs at the cost of growth and reproduction, thus affecting the fitness of these organisms (Geller 1990, Peterson & Quammen 1982, Kamermans & Huitema 1994, Irlandi & Mehlich 1996).

The bivalve *Donax denticulatus* Linnaeus, 1758, locally known as “chipi-chipi” occurs intertidally on sandy beaches throughout the Caribbean all year long (Wade 1969). In Venezuela, it is commonly found in the intertidal zone of fine and medium grain dissipative sandy beaches in the central west coast, together with the

bivalves *Donax striatus* and *Tivela mactroides* (De Mahieu & Gamba 1980, Penchaszadeh 1983, Penchaszadeh et al. 2000). *D. denticulatus* is an important species in the food chain as a primary consumer of phytoplankton and detritus and is also eaten by a wide range of predators including the fishes *Menticirrhus littoralis*, *Conodon nobilis*, *Trachinotus carolinus*, *Trachinotus goodei* and *Unbrina coroides*, and the ghost crab *Ocypode verreauxi* (Penchaszadeh 1983, Riera 1995).

The siphons of this species are both flexible and extensible as are those of *Donax hanleyanus* Philippi 1847 (Luzzatto & Penchaszadeh, 2001) and other tellineacean bivalves. They are comprised of 6 primaries, 6 secondaries, 12 tertiaries, and 24 quaternaries tentacles (Wade 1969). When buried, the siphons of *D. denticulatus* extend through the sediment into the water column and look like a white crown from above. This highly ramified structure prevent large particules (>250 µm) from entering into the stomach (Wade 1969).

In this study, we followed a detailed examination of artificially amputated siphon regeneration of *D. denticulatus*, to establish time of regeneration and the effects of amputation on the morphology of siphons.

MATERIALS AND METHODS

Individuals of *D. denticulatus* were collected at the intertidal zone of Tucacas beach located in the central west coast of Venezuela (10°45'55"N, 68°19'24"W). Organisms with a shell length of 1.5–2.0 cm were collected to ensure that all were already sexually developed. They were transported to the laboratory in an icebox with wet sand. In the laboratory, 2 groups consisting of 50 animals each (control and experimental groups) were placed separately in aquaria with aerated seawater at 35‰, 23 °C and a layer of sand deep enough for burrowing. They were fed with Advanced Invertebrate Formula (Marine Enterprises, Inc.) once a day. The

animals were maintained for acclimation under these conditions for 5 days.

After this period, the experimental organisms were placed in Petri dishes with seawater. Once the siphons were extended, an anesthetic solution of magnesium chloride 7.5% in seawater was slowly added, and then the petri dish was placed in the refrigerator at 4 °C for 20 min. After this treatment, the siphons are completely elongated and do not retract in the shell, so we proceeded to cut the siphon tip with dissecting scissors. The tips were fixed in a glutamine-acetate buffer containing 6% formalin (Miloslavich & Penchaszadeh, 1997) and kept in the refrigerator. The animals were left to recover in their aquaria and then sacrificed in groups of 2 individuals twice a day (9 AM and 5 PM) during a 10-day period and then at day 30, cutting and fixing the tips by the described procedure. Observations of the fixed tips were done with a stereoscopic microscope. Also, we observed the siphons of the recovering animals to corroborate activity and functionality.

RESULTS

The regeneration sequence is shown in Figure 1. In the anesthetized individuals, the siphon slowly retracted into the shell after the cut and remained retracted for about 30 minutes. After this time, the siphon extended and started to function creating inhalant currents but unable to select or filter particles; some siphons were active up to 5 hours after the cut, and were able to select particles 72 hours after amputation. The siphon showed full functionality on the 5th day. Regarding the regeneration sequence, the 1st day (24 hours after the cut) the process was slow and only the rudiments of the primary tentacles were visible (see Figs. 1c). Within the 2nd and the 3rd day a fast transformation of the siphon was observed, with the regeneration of secondary tentacles (see Fig. 1d to f). The regeneration process was completed within the 5th day, however the regenerated siphon showed less ramification than the unamputated one (see Fig. 1h). A schematic sequence of regeneration is

Figure 2. Schematic sequence of inhalant siphon regeneration 5 h after amputation, 24 h after amputation, 72 h after amputation, and 5 days after amputation. P, primary tentacles; S, secondary tentacles; T, tertiary tentacles; Ti, siphon tissue; I, internal cavity.

shown in Figure 2, highlighting the regeneration process of primary, secondary, and tertiary tentacles.

Between the 5th and the 9th day no significant transformations were detected (Fig. 3a to c). One month later, the siphon had the same as the 5th day (see Fig. 3d). At the end of experiments, all regenerated siphons were less ramified than unamputated ones, even 1 month after amputation.

DISCUSSION

As noted earlier, siphons are responsible for important activities such as feeding and defecation, therefore its ablation should have direct impact on these activities. Wade (1969) noted that after amputation, particles as large as 700 μm were found in the mantle cavity of *D. denticulatus*, forcing the organism to invest effort in extracting these particules out of the mantle, and temporarily suspending feeding activity. Additionally, regeneration itself is an energy consuming process. Artificially amputated individuals of *Donax serra* showed a decrease in growth rates when compared with nonamputated individuals (Hodgson 1982). Pekkarinen (1984) also registered significant growth rates differences in individuals of *Macoma balthica*, a tellinacean bivalve, when inhalant siphon was removed. The slow process of regeneration observed within the first 24 hours after amputation in our experiment, are probably due to the malfunctioning of the siphon, in the absence of developed tentacles, therefore limiting the food and oxygen intake of amputated individuals. Additionally, Pekkarinen (1984) observed that just after amputation, siphon muscles contract to close the wound, preventing the loss of hemolymph, but also preventing the water to flow through the siphons.

Luzzatto and Penchaszadeh (2001) studied changes in regen-

eration rates of inhalant siphon of *Donax hanleyanus*, and showed that this process had a sigmoidal behavior. Within the first hours, regeneration rate was slow, but then increased exponentially between the 1st and the 3rd day after amputation, until the secondary tentacles were developed. After that, regeneration rate slowed until the siphon became fully active in selecting particules (5 days after amputation). Siphons of *D. denticulatus* also showed fast regeneration rate between 24 and 72 hours after amputation (see Fig. 1d–f), with a full development of primary, secondary, and tertiary tentacles on the 5th day after amputation (see Fig. 1h). Pekkarinen (1984) reported full regeneration after 7 days for *M. balthica*.

Close observation of regenerating siphons allowed us to conclude that the highest regeneration occurred at the beginning of the process, with a short lag-time period of 24 hours, in which functionality was reestablished. The most notorious morphologic transformations were detected within the first 72 hours of regeneration, with fast regeneration of primary and secondary tentacles, whereas the regeneration of tertiary tentacles extended for a longer period of time (5 days). Therefore, primary and secondary tentacles must play an important role in providing basic functionality to the siphon, as well as to the whole organism.

ACKNOWLEDGMENTS

We are indebted to the students of the Marine Biology course of the Universidad Simón Bolívar who helped collecting the animals at Tucacas beach. This work was partially supported by a Decanato de investigación y Desarrollo (USB) grant to the Grupo de Ciencias Marinas (G-003) and by cooperative program Venezuela-Argentina funded by Fundación Antorchas.

FIELD AND LABORATORY OBSERVATIONS OF THE MASS MORTALITY OF THE YELLOW CLAM *MESODESMA MACTROIDES* IN SOUTH AMERICA: THE CASE OF ISLA DEL JABALÍ, ARGENTINA

SANDRA FIORI,* VÍCTOR M. VIDAL-MARTÍNEZ,² RAÚL SIMÁ-ÁLVAREZ,² ROSSANNA RODRÍGUEZ-CANUL,² MA. LEOPOLDINA AGUIRRE-MACEDO² AND OMAR DEFEÓ^{2*}

²CINVESTAV Unidad Mérida, A.P. 73 Cordemex, 97310 Mérida, Yucatán, México

ABSTRACT Since the mid-1990s, the yellow clam *Mesodesma mactroides* (Deshayes, 1854) has experienced mass mortalities throughout its biogeographic range (23 °S to 41°S) along Atlantic exposed sandy beaches of South America. However, there is no information about the potential causes underlying these large-scale events. In the summer of 2002, a sudden massive mortality almost decimated the yellow clam population located to the south of Isla del Jabalí (Argentina), at the southern edge of its geographical range. Field observations showed a drastic decrease in abundance from 2000 to 2002, without recovering since then. Mortality sequentially occurred at the beach in a north-south direction, following the same trend as in the large-scale event. Significant differences in individual size were found between dead and live clams with the largest individuals of the population being the most affected. Histologic analysis revealed the presence of a meront stage of an unidentified coccidian parasite in the epithelium of the middle intestine of 3 of the 14 clams examined. Necrosis was found in gills and stomach in 13 of the 14 clams examined. The results suggest that these parasites could play a role in the massive mortality events of the yellow clam populations all along South American sandy beaches since 1993. These findings provide an alternative explanation to the widely held notion that mass mortalities in sandy beach macrofauna are due to harmful algae blooms.

KEY WORDS: mass mortalities, bivalves, *Mesodesma mactroides*, coccidian parasite, sandy beaches, Argentina

INTRODUCTION

The yellow clam *Mesodesma mactroides* is an intertidal bivalve distributed along the warm-temperate Atlantic coast of South America, from Sao Paulo State, Brazil (24 °S) to the south of the Buenos Aires province, Argentina (41°S; Fig. 1a). Yellow clam populations prosper primarily in the intertidal zone of microtidal dissipative beaches with gentle slope, fine sand, heavy wave action, and a wide surf zone often characterized by high primary production by surf diatoms (Defeo & Scarabino 1990). The yellow clam has supported recreational and artisanal fisheries of high socio-economic importance (Defeo et al. 1993, Castilla & Defeo 2001).

Since 1993, episodic mass mortalities have decimated yellow clam populations throughout its entire geographic range. These events occurred mainly between late spring and early summer, following a sequential north-south direction (see Fig. 1a). Mortalities occurred first in Brazil in March 1993 (Odebrecht et al. 1995), then in Uruguay in December 1994 (Méndez 1995) and last in Argentina from September to November 1995 (Fiori 1996, Fiori & Cazzaniga 1999). These mass mortalities have prevented the rehabilitation of yellow clam populations throughout its range (Fiori 2002, Defeo 2003). These large-scale events have not been successfully explained, mainly because of the lack of sampling opportunities concurrent with the occurrence of these sudden phenomena. Odebrecht et al. (1995) conjectured that high abundance of dinoflagellates was a source of yellow clam mortality in Brazil, but when the mass mortality occurred in Uruguay, bioassays indicated that paralytic shellfish toxins were not present (Méndez 1995). The same held true for Argentinean coasts, where metal contamination, phytotoxins, abnormal phytoplankton composition,

and protozoan tissue-parasites were discarded as causative factors (Fiori & Cazzaniga 1999).

In January 2002 (austral summer), a mass mortality occurred in the southernmost and isolated yellow clam population located at the south of Isla del Jabalí, Argentina. During this event, living organisms were recovered for histologic study. Here we describe the mass mortality event at Isla del Jabalí. First, we quantify the magnitude of the event in terms of population density and structure. Second, we perform a histologic examination of the visceral mass of clams, including gills, digestive gland and stomach. Finally, we discuss the large-scale implications of these findings.

MATERIALS AND METHODS

The study area located to the south of Isla del Jabalí (Argentina: 40°33'S; 62°14'W) is a continuous sandy beach, ca. 15 km long, with gentle slope ($1.64 \pm 1.16^\circ$), fine sand (mean grain size = 0.20 ± 0.91 mm), strong wave action and high salinity (34.3 ± 0.17 ppm) (Fiori 2002). The mean air temperature fluctuates between 6 °C (winter) and 19 °C (summer). During the mortality event, a stratified random sampling was carried out in 3 beach sites separated by 4 km and located in the north-south direction, thereafter mentioned as sites 1, 2 and 3 (see Fig. 1b). A total of 18 random parcels were located in the mesolittoral area inhabited by the yellow clam, using 50 × 50 cm frames and digging up to a depth of 50 cm. The sediment from each parcel was sieved through a 1-cm mesh and all clams retained were counted, measured with calipers (0.1-mm precision) and discriminated as dead or alive. All clams collected were used to estimate the length frequency distribution (LFD) of the population discriminated by site and clam status: (1) dead clams, in life position into the sediment with the foot and siphons everted and the shell paired open, or with decomposed flesh; (2) alive clams, with closed shell and ability to burrow themselves in the substrate. We did not consider empty valves placed on the sand because we cannot attribute incontestably if

these valves came from the mortality event. Two-way ANOVAs were used to test for differences between density and clam length, with status and beach site as main factors. A simple length-based survival ratio SR was applied as $SR = 1 - D_i/(D_i + L_i)$, where D is the number of dead clams and L is the number of live clams for each length class i . The analysis was compared with density estimates obtained in summer of 2000, following the same stratified random sampling detailed above.

A total of 14 clams collected in sites 2 and 3 (we did not find clams in site 1) were fixed after shucked in 10% buffered formaldehyde in seawater immediately after collection and transported to CINVESTAV-Merida (Mexico) for histologic examination. After arrival, formaldehyde was washed out and replaced with Davison's AFA solution for 4 days. Then, a section of the visceral mass of each preserved clam that contained gills, digestive gland and stomach was embedded in paraffin and cut at 5 μ m thickness. The tissue sections were affixed to glass slides and stained with hematoxylin and eosin (Howard & Smith 1983). A frequently causal agent of mass mortality in oysters, clams, cockles, scallops, and abalones documented worldwide is the Apicomplexan protozoan *Perkinsus* spp. (Bower et al. 1994). Unfortunately, thioglycollate fluid or other culture media to determine the presence of these Apicomplexan parasites were not available during the mortality event. In this case, we had to rely on the histologic findings. Samples of clam tissue embedded in paraffin were also sent to Dr. Eugene Bureson (Virginia Institute of Marine Science) for detecting *Perkinsus* spp. using a genus-specific DNA probe. A *Perkinsus marinus*-specific PCR test based on the primers of Robledo et al. (1998) was also undertaken at CINVESTAV Merida. Finally, digital photographs of the parasites were sent to other experts in coccidian parasites (Dr. Donald Duszynsky, University of New Mexico, USA; Dr. Iva Dykova, Institute of Parasitology of the Academy of Sciences of the Czech Republic) for identification.

RESULTS

Dramatic declines in abundance of yellow clam were observed in two of the three sites sampled at Isla del Jabali. About 15 km of the beach was covered by an accumulation of empty shell, particularly on the supralittoral zone (Fig. 2). The moribund yellow clam remained buried into the sand, even though they weakly retracted the siphons after a mechanical stimulus. Table 1 shows the clams density before and after the mass mortality event. Density significantly differed between sites ($F_{2,30} = 18.31$; $P < 0.001$), but did not differ between clam status ($F_{1,30} = 0.77$; $P < 0.973$). The 'site \times status' interaction factor was significant ($F_{2,30} = 3.95$; $P = 0.03$), as a result of the contrasting patterns in clam status between sites 2 and 3 (LSD test, $P < 0.01$; see Fig. 3a).

In site 2, individual size of live clams were in the range 45–67 mm (mean \pm SD: 61.8 ± 5.9 mm), whereas dead clams varied between 51 and 76 mm (65.3 ± 4.1 mm). In site 3, dead yellow clam varied between 40 and 77 mm (mean \pm SD: 65.2 ± 8.3 mm), whereas live clams were in the range of 54–80 mm (67.3 ± 6.1 mm). The survival ratio SR markedly differed between sites (see Fig. 3b): in site 2, SR exponentially decreased ($R^2 = 0.69$; $P < 0.01$) towards larger clam sizes, with 0% survival at sizes >70 mm; in site 3, size-specific SR were significantly higher than in site 2, and linearly decreased ($R^2 = 0.40$; $P = 0.02$) towards oldest length classes, reaching values as high as 67% at 76 mm. The two-way ANOVA revealed significant differences in mean size between beach sites ($F_{1,272} = 5.74$; $P < 0.017$) and clam status ($F_{1,272} = 5.06$; $P < 0.025$), while the 'site \times status' interaction factor was not ($F_{1,272} = 0.53$; $P = 0.468$). This means independence of the effect of "site" on the level of the factor "status", reflected in highest sizes at the northern site and for dead clams (LSD test; $P < 0.01$).

Eleven of the 14 (78%) clams examined presented necrosis in the stomach (Fig. 4a), which was characterized by necrotic hemocytes and pycnotic cells (see Fig. 4a). Thirteen of the 14 (93%) clams also presented necrosis in gills (see Fig. 4b). The ciliate *Trichodina* sp. was found in one of the 14 (7%) clams. Samples did not react with the *Perkinsus* genus-specific DNA probe, nor were positive for the PCR test for *Perkinsus marinus* either. The parasite in Figure 4c was a meront stage of an unidentified coccidia 21–16 μ m long and 13–17 μ m wide ($n = 10$), with

Figure 2. Dead yellow clams, *Mesodesma mactroides*, during the massive mortality event in February 2002 at Isla del Jabali.

16–21 merozoites per meront. The merozoites were elongated with 4–5 μ m long and 2–3 μ m wide ($n = 10$). This parasite was present in 3 of the 14 (21%) clams examined. There was necrosis of the tubules of digestive diverticula in the infected host (see Fig. 4d).

DISCUSSION

We provide the first observations for the mass mortality that decimated the yellow clam population at the southernmost edge of its range. Sites 1 and 2 showed a dramatic decrease in density, whereas site 3, situated southwards, appeared to be unaffected in the short term during the mortality event. This gives support to the directional event from north to south, as occurred on a biogeographic scale. However, it is worth mentioning that, after that date, all clams in the three sites died and up to now (June 2004) the recovery of the population has been negligible (Fiori, personal observation). Analysis of the LFDs and the size-based *SR* showed

that larger clams were more susceptible than smaller ones. Survival significantly decreased towards larger sizes, and this was consistent for the two main beach sites analyzed, even though the declining ratio was exponential in site 2 and linear in site 3, suggesting again a north-south direction of the mortality event.

The histologic analysis revealed the presence of gill, stomach, and intestine necrosis. It is difficult to link this tissue damage to the coccidian parasite found, because it was present only in 3 of the 14 clams examined. However, it is not possible to discard the possibility either, because the collected clams were survivors of the massive mortality. In these circumstances, it would be reasonable to expect that collected specimens should have low infection levels. In addition, Cremonte and Figueras (2003) reported, for the first time for this species, coccidian and gregarines in a sample of yellow clam from Isla del Jabalí, which was taken 2 years before the mass mortality. Coccidians were found in 93% of the 32 clams processed. Furthermore, several authors have found that mass mortalities of other mollusks (scallops) in the Atlantic coast of America and Spain have been related to coccidian parasites, especially those of the genera *Pseudoklossia* and *Margolisella*. These parasites produced extensive destruction of kidney and digestive gland of their hosts (Leibovitz et al. 1984, Desser & Bower 1997, Carballal et al. 2001). Unfortunately, it was not possible to examine kidney because this tissue did not appear in the fixed material. However, it is not possible to attribute the necrosis to bad fixation of the biologic material because all clams were properly shucked and fixed. Clearly, more research is needed to determine the relationship between this coccidian parasite and the tissue damage observed.

The mass mortality at Isla del Jabalí occurred in summer, in agreement with the other yellow clam mortality events that have occurred throughout the species range (Fiori & Cazzaniga 1999). This indicates high vulnerability of the yellow clams during this season, concurrently with high temperature, salinity and species density (Fiori 2002). A possible explanation for this pattern could be an increase in the vulnerability of the parasitized clams with respect to the unparasitized ones. For example, *Perkinsus*-associated mass mortalities have been observed with high values of temperature, salinity, and species density (Choi et al. 2002). Mass mortalities tend to occur in summer (Chu et al. 1996, Choi et al. 2002) or even as a result of increasing winter water temperatures (Cook et al. 1998). However, to the best of our knowledge, there are not published studies on the seasonal variation of the infection parameters (prevalence, mean intensity) or mortality produced by coccidian parasites of bivalves, and its association with environmental factors such as temperature or salinity remains unknown.

One of the most important characteristics of the mass mortalities affecting the yellow clam throughout South America is its strong host specificity, as other members of the macrofauna, including the very abundant sympatric suspension feeders in Uruguay and Brazil, *Donax hanleyanus* (Defeo & de Alava 1995) and *Emerita brasiliensis* (Defeo & Cardoso 2002) were not affected (Defeo 2003). As transplanting of clams has not been performed, it seems that the mortality agent is transported by littoral currents, suggesting a strong dispersal capability and tolerance to surpass zoogeographic barriers like the estuarine environments Rio de la Plata, Bahía Blanca, and Bahía Anegada, which present highly variable physico-chemical conditions, especially in salinity.

Our results, even preliminary, provide the first potential explanation to the mass mortality event in this species. Further studies involving immunologic and molecular biology techniques are

needed to provide conclusive results about the role of this parasite in the massive mortality of this endangered species (Fiori & Cazaniga 1999).

IMPACT OF GREEN CRAB (*CARCINUS MAENAS* L.) PREDATION ON A POPULATION OF SOFT-SHELL CLAMS (*MYA ARENARIA* L.) IN THE SOUTHERN GULF OF ST. LAWRENCE

TREVOR FLOYD AND JIM WILLIAMS*

Department of Biology, St. Francis Xavier University, Antigonish, Nova Scotia, B2G 2W5, Canada

ABSTRACT A caging experiment was carried out on an estuarine mudflat in Pomquet Harbour, Nova Scotia, Canada from late May to early September 2001. Six replicate 0.83 m² cages were set up for each of the following treatments: low predator density cages with one green crab (*Carcinus maenas*), high predator density with five green crabs, enclosure cages with no crabs, and control cages with sections of the sides removed. In addition, six 0.83 m² sections of exposed mudflat served as further controls. Green crabs significantly reduced numbers of small (<17 mm) soft-shell clams (*Mya arenaria*), removing ca. 80% of the small clams within low and high predator cages. There was no significant difference in large (>17 mm) soft-shell clam densities for any of the treatments. Green crabs consumed small clams at a minimum rate of 3.1 clams/crab/day and a maximum rate of 21.8/clams/crab/day. Predation intensity did not vary with density of crabs within cages.

KEY WORDS: green crab, *Carcinus maenas*, invasive, soft-shell clam, *Mya arenaria*, predation, caging experiment

INTRODUCTION

The establishment of an invasive or non-indigenous species can result in significant ecological changes in the receiving environment. The green crab, *Carcinus maenas* (Linnaeus), is an example of a very successful marine invasive species. After establishment in a new environment, green crabs have been shown to effect changes at the individual, population and community levels (Hughes & Elner 1979, Grosholz et al. 2000, Trussell & Smith 2000, McDonald et al. 2001).

Although green crabs directly and indirectly affect many benthic organisms, bivalves are usually the preferred prey (Ropes 1968, Elner 1981, Grosholz & Ruiz 1995) and exhibit dramatic post-invasion changes. Grosholz et al. (2000) found that invasive green crabs exert predatory control on the native clams *Nutricula tantilla* (Gould) and *Nutricula confusa* (Gray), population levels of these clams declined drastically within 3 years of the arrival of green crabs, and have shown no sign of recovery since the invasion. In Tasmania, Walton et al. (2002) used both field observations and manipulative field experiments to investigate green crab predation on the venerid clam *Katelysia scalarina* (Lamarck). They found that green crabs exerted considerable predatory pressure on smaller clams (<13 mm shell length). On the east coast of North America, declines in population sizes of the soft-shell clam (*Mya arenaria* Linnaeus) have been linked to the arrival of the green crab (Glude 1955).

It has been established that soft-shell clams are a significant prey item for green crab. Glude (1955) found excellent survival and growth in areas where green crabs were excluded by fencing or screening. Ropes (1968) examined approximately 4000 green crab stomachs, and concluded that soft-shell clams were an important component of the crab's diet in Massachusetts. He also reported that the frequency of *M. arenaria* remains in green crab stomachs was highest during September to November, and suggested that this was due to the abundance of juvenile clams in the fall. In a similar study from Port Hebert, Nova Scotia, Elner (1981) also found that soft-shell clams were an important prey item for green crabs. However, in contrast to the New England study, Elner (1981) reported significant predation on soft-shell clams in May and August.

In summary, correlations have been demonstrated between green crab arrival and declines in abundance of soft-shell clams. Furthermore, gut content studies have shown that soft-shell clams are a significant prey item for green crabs. We used an *in situ* caging approach to investigate the timing, nature, and extent of green crab predation on a population of soft-shell clams. Specifically, we wanted to: (1) experimentally determine the extent of green crab predation on soft-shell clams during the summer; (2) determine if green crab predation on soft-shell clams was size selective; and (3) determine if there was a relationship between green crab density and predation rate.

METHODS

Pomquet Harbour, Nova Scotia, is a shallow estuary (tidal amplitude of approximately 1 m) that is connected by a narrow channel with St. Georges Bay (Fig. 1). The study site was a 7 × 11 m section of a lower intertidal flat of slightly gravelly sand located near the mouth of the Pomquet River (45°36.19'N, and 61°36.19'W). The surrounding terrestrial vegetation was predominantly *Spartina alterniflora* (Loisel) with patches of *Solidago sempervirens* (L.), *Convolvulus arvensis* (L.), *Festuca pratensis* (Hudson), and *Rosa virginiana* (Mill.). Salinity and temperature at the site were measured from high tide to low tide for one spring tide on August 5, 2001. The surface salinity ranged from 26.0‰ to 23.2‰ and the bottom salinity ranged from 29.0‰ to 25.1‰ during the ebb. The surface temperature ranged from 21.2°C to 26.3°C and the bottom temperature ranged from 21.8°C to 26.3°C. The water depth in the middle of the study site was approximately 35 cm at high tide, and the mudflat was approximately 20 cm above sea level at low tide.

On May 22, 2001, limited preliminary samples were collected to identify the macrofauna, with emphasis on *M. arenaria*. The sampling was limited partly to minimize disturbance on the relatively small clam flat, and partly because the design was not based on comparisons of pre- and post-experimental conditions. Six core samples (10 cm diameter, 20 cm depth) were taken from randomly selected areas around the proposed location for the cage matrix. The 6 core samples were washed through a series of graded sieves to a bottom mesh size of 0.5 mm, and all retained organisms were removed and preserved. This mesh size has been shown to yield close to 100% of the macrofaunal species and over 95% of the biomass (Reish 1959). Also, sediment from a 1 m² section of the

Figure 1. Map of study site in north eastern Nova Scotia, Canada. Expanded panel indicates cage experiment site in Pomquet Harbour.

site was removed to a depth of 20 cm and passed through a 1.27 cm sieve to collect the large *M. arenaria* (clams >17 mm). We designated clams larger than 17 mm as large soft-shell clams for the purpose of this experiment. This size represents the maximum observed size of that year's set of small, recently settled clams.

Cages were $0.91 \times 0.91 \times 0.30$ m high, and were constructed of plastic-coated wire, with a square mesh opening of 1×1 cm. Treatments were as follows: 6 enclosure cages (E), with no predators added, 6 control cages (C1) with 20×70 cm portions of each side removed allowing for unrestricted predator movement, 6 undisturbed mudflat controls that were outside but adjacent to the cage matrix (C2), 6 low-predator-density cages (D1) with 1 crab added, and 6 high-predator-density cages (D2) with 5 crabs added. The low predator densities of 1.2 crabs/m² reflects mark and recapture data acquired the previous year in a similar habitat in an adjacent harbor (Campbell 2000). The high predator density of 6.1 crabs/m² reflects green crab densities estimated by Young et al. (1999) for a New England salt marsh tidal creek.

To reduce the potential impact of any environmental heterogeneity of the mudflat, a randomized block design was used for location of cages. During a spring low tide on May 23, 2001, the cages were deployed in a 6×4 rectangular matrix, with the four treatments randomly assigned to a position in each row (= block), and 1 m between all the cages. The rows were oriented perpendicular to the gradual slope of the mudflat, resulting in approximately 10 cm height difference between the highest and lowest cages. The cages were pushed into the sediment to a depth of 20 cm, allowing a 10-cm space above the substratum. Green crabs trapped the previous day were added to the appropriate cages by cutting a small flap in the cage, adding crabs, and closing the flap with plastic cable ties. Only male crabs (53.5 ± 5.22 (SD) mm, ranging from 44 mm to 65 mm in CW) with complete pairs of chelipeds and sets of walking legs were used in the enclosures. The crabs in the D1 and D2 cages were checked every spring tide throughout the next 3 months by gently probing the mud with a wire probe. Following Gee et al. (1985), any crab mortality during the experiment was noted, but crabs were not replaced.

Between August 21 to 23 (approximately 3 mo after deployment), the cages were removed from the substratum. To test for cage-induced physical changes to the site, 4 random sediment samples were taken (5 cm deep, 2.5 cm diameter) from each cage area, as well as the 6 C2 plots sampled outside of the cage matrix. These samples were frozen and later dried at 70°C for 7 hours. A weighed subsample was heated in a 500°C muffle furnace for 7

hours and re-weighed to determine the percent organic content, which was compared among treatments using the Kruskal-Wallis non-parametric H-test. Following Folk (1974), subsamples of the remaining sediment were then dry sieved through a series of Wentworth graded sieves to determine the size distribution of the particles. These size distributions were then compared with check for cage effects.

Three large cores (10 cm diameter, 20 cm depth) were taken from randomly selected locations within each cage (Hall et al. 1990). To avoid edge effects, cores were never taken within 15 cm of the sides of the cages (Kent & Day 1983). The core samples were sieved to a bottom mesh size of 0.5 mm, and clams preserved and counted. After coring, all sediment inside the cages was excavated to a depth of 30 cm and sieved through a 1.27-cm coarse sieve to collect large soft-shell clams. Large clams were counted and a concentric ring analysis was used to determine age (Newcombe 1936). In addition to sampling of cage sites, the six C2 plots, which were chosen randomly on all sides of the cage matrix, were subjected to the same sampling regimen.

Core sample data was used to determine densities of small soft-shell clams (clams <17 mm in length). Since three cores were taken from each cage, the arithmetic means of the cores were used in the analysis to avoid problems of pseudoreplication (Gee et al. 1985). The Shapiro-Wilk method was used to test for the normality of the count data for both size classes of clams. Data for large and small soft-shell clams was normally distributed ($P = 0.13$ and 0.42 respectively). An ANOVA appropriate for a randomized block design and the Tukey multiple comparison test was used to test for significant difference among treatments. Initially we only included the 4 cage treatments E, D1, D2, and C2 in the analysis. Because no block effect was detected in the initial analysis ($P = 0.157$), a subsequent analysis was run with the additional data from the mudflat C2.

On May 30, 2002, the study site was again sampled to determine the fall/winter survival of the 2001 summer set of small soft-shell clams. Six random core samples were obtained adjacent to the study site and clams were removed, measured, and counted.

RESULTS

No noticeable scouring or deposition of sediment from water movement was observed in cages throughout the experiment. Sediment organic content averaged $3.30\% \pm 0.57$ (SD), with no significant difference among treatments ($\chi^2 = 2.612$, d.f. = 5, $P =$

0.625). Based on particle size distribution, the sediment for the study site can be classified (Folk 1974) as slightly gravelly sand. Particle distribution analysis showed no difference between treatments (Fig. 2). No long-term fouling by growing or drift algae occurred on the cages.

The core samples taken before the cages were deployed yielded 3 species of macrofauna: the bivalves, *M. arenaria* and *Macoma balthica* L., and the polychaete, *Hediste diversicolor* Muller. Soft-shell clams made up more than 95% of macrofaunal numbers and biomass. Large soft-shell clams had a pre-experiment density of 21/m². There were no small clams found at this time.

No significant difference was found among treatments for large soft-shell clams, both when only cage data were compared (Fig. 3, $P = 0.101$) and when undisturbed mudflat C2 data were included ($P = 0.134$). Large soft-shell clam densities ranged from 11 to 24 clams/m², and had a mean density of 19.2 ± 6.05 (SD) clams/m², (see Fig. 3). A significant difference was found among treatments for small soft-shell clams, when the cage data were compared, and when the undisturbed mudflat C2 was included (Fig. 4, $P < 0.001$ for both comparisons). Specifically, D1 and D2 enclosures had significantly fewer small clams than all other treatments but did not differ from each other. Small soft-shell clam densities ranged from 305/m² (D2 enclosure) to 1712 clams/m² (enclosure).

Some crab mortality occurred in enclosure cages during the last 3 weeks of the experiment, thereby making calculation of consumption rates difficult. Average estimated consumption rates were calculated using the initial and final crab densities. Two of six crabs in the D1 cages died during the last month, yielding a final D1 density of 0.80 crabs/m². In the D2 treatments, which started with 5 crabs in each cage, the number of surviving crabs were 0, 1, 2, 2, 3, and 3 crabs, yielding a final D2 density of 2.16 crabs/m².

Because no significant difference was detected among treatments for large soft-shell clams, the age analysis data were pooled to provide a picture of the age structure at the study site (Fig. 5). The 4-year and 5-year age classes dominated the sampled soft-shell clams on the study site, with very few clams aged 1, 2, and 3 years in the population. The spring 2002 sampling yielded 148 small soft-shell clams/m². This spring density was significantly

less than the late summer density of approximately 1500/m², and represents nearly 90% fall/winter mortality.

DISCUSSION

Small Soft-shell Clams

We found clear evidence of significant green crab predation on soft-shell clams with small clam densities within enclosures significantly lower than in all other treatments. This concurs with a summary of green crab feeding studies provided by Cohen et al. (1995), in which they report that green crabs select soft-shell clams less than 20 mm in length. Welch (1968) found that green crabs regularly destroyed sets of small clams, and Beal et al. (2001) states that losses of recently settled soft-shell clams coincided with the appearance of predators, including green crabs, within experimental units. Glude (1955) found a daily consumption rate of 15 small clams/crab in the laboratory. Our ability to calculate daily consumption rates is somewhat hampered by the crab mortality that occurred in the last 3 weeks of the study, and our inability to

Figure 4. Densities (numbers of clams per square meter) of small soft-shell clams (<17 mm shell length) from experimental cage plots. Bars represent means, error bars represent standard deviations of means. Different upper-case letter above bars indicates a significant difference between means.

Figure 5. Observed densities of each age group of large (>17 mm shell length) soft-shell clams from the experimental cage site. Each bar represents the density of one age class, determined by the total counts from all 30 cage sites divided by the total surface area exhumed (approximately 25 square meters).

determine when clams were consumed. However, we can calculate a range by assuming either that all clams were consumed prior to crab mortality, or that all clams were consumed by the remaining crabs after the mortality occurred. Daily consumption rates were between 14.5 and 21.8 small clams/crab in the one crab treatments and 3.1 and 8.3 small clams/crab in the five crab treatments. These ranges are the first *in situ* estimates of green crab consumption rates on small soft-shell clams.

One of the objectives of this research is to assess the extent of summer predation on soft-shell clams. A comparison of clam densities among enclosure cages, control cages, and open mudflat samples provide estimates of overall predation, and also gives some clue as to the type of predator. The control cages were designed to exclude avian predators, but allow access by fish and invertebrates. The open mudflat sites were available to all predators. No statistically significant differences were detected between enclosure clam densities and densities from the two types of control samples. Even though our results demonstrate that green crabs are capable of harvesting a significant number of small soft-shell clams from the flats, this activity does not take place during the summer. Ropes (1968) found soft-shell clams occurred most frequently in green crab stomachs during September to November. As well, Glude (1955) found that strongly recruiting populations of small soft-shell clams had disappeared by the autumn where green crabs were present. These reports, as well as this study, are in contrast with Elner (1981), who found that *M. arenaria* were a large component of green crab diet in both May and August. The difference in the timing of crab predation on soft-shell clams in Elner's (1981) work may be due to much cooler summer water temperatures along the southeastern coast of Nova Scotia, as compared with the two New England studies, and our estuarine site in Pomquet Harbour. On August 5, maximum bottom temperatures at our study site were 26°C, and could well have exceeded 30°C in August. In the late fall, when the water temperatures are lower, green crabs may increase foraging on the clam flats. At this time, the crabs would also benefit from the increased size of young-of-the-year clams. Extensive pitting attributed to green crab foraging has been observed on other Pomquet Harbour mudflats during the late autumn and early winter (P. J. Williams, unpublished data).

To obtain an estimate of small clam mortality during the fall/winter period, we sampled the study site the following spring (2002) before the green crabs became active. We found that approximately 90% of the small soft-shell clams had been removed in the period from August 2001 to May 2002. Although we cannot partition the removal among migratory birds, fish, green crab, other invertebrates, or physical factors such as ice scour, the loss is comparable with the 80% mortality we observed within green crab enclosures.

There was no difference in small soft-shell clam abundance between the low density (1 crab) and the high density (5 crabs) crab enclosures. Crab mortality during the experiment may have compromised our ability to detect differences. In retrospect, an experiment with a shorter time frame would have been better to elucidate density-related predation rates. However, even green crab densities of 0.8/m² can result in effective removal of 80% of small clams.

Large Soft-shell Clams

In contrast with the small soft-shell clam results, we found negligible predation by green crab on large soft-shell clams. The apparent selection of small clams over large ones has been suggested for green crab feeding on soft-shell clams (Welch 1968), and indeed fits a general pattern for crustaceans feeding on molluscs (Smith et al. 1999). There are a number of factors that might have led to the size discrimination. Green crabs are both tactile and chemosensory hunters (Cohen et al. 1995), and probably detect clams by following plumes from exhalant siphons, and/or coming in contact with siphons or siphon holes while probing sediment with appendages (Dare & Edwards 1981). During this study, the densities of small clams were much higher than the large clams, and therefore green crabs would have a higher encounter rate with the smaller clams. Studies that have addressed crab predation on molluscs from an energy optimization viewpoint (Elner & Hughes 1978, Juanes 1987) suggest that thicker shells in larger bivalves may lead to increased breaking time/energy expenditure, and may also result in chela damage for the crab. However, laboratory experiments have shown (Ropes 1968) that green crabs are able to open and consume soft-shell clams that were longer than the carapace width of the crabs. In this study, the mean length of the large soft-shell clams was 54.7 ± 6.79 (SD) mm, and only 17 of the 463 clams sampled were larger than the 65 mm carapace width of the crabs used. Therefore, shell thickness was probably not a factor in green crabs selecting small clams. We feel that burial depth of the clams was the basis for the selection of small clams by green crabs. Zaklan and Ydenberg (1997) found similar results in predation experiments on soft-shell clams by red rock crabs (*Cancer productus* Randall) and attributed large clam survival to a depth refuge. Larger soft-shell clams are usually found deeper in the sediment than small clams (Blundon & Kennedy 1982, Zaklan & Ydenberg 1997), and we commonly found large clams at depths of 30 cm when sampling. Even though green crabs can burrow effectively, digging pits up to 15 cm deep (Ropes 1968, Ropes 1988, Lindsay & Savage 1978); our results suggest that green crabs are not effective predators at the depths where large soft-shell clams reside.

Large Soft-shell Clam Population Structure

The large soft-shell clam population at our experimental site was dominated by the 4-year and 5-year age classes, with weak

year classes for clams aged 1, 2, and 3 years. Yearly variability in age class strength, attributed to changes in reproductive success, has been well documented in soft-shell clams (Kube 1996, MacKenzie & McLaughlin 2000, Strasser et al. 2001), but the weak year classes over the previous 3 years correspond with the period in which green crabs became abundant in Pomquet Harbour (P. J. Williams, unpublished data). An alternative explanation involves the recent outbreak of Hemic neoplasia that has been reported by McGladdery et al. (2001) in soft-shell clams in Atlantic Canada, however incidence of this disease was highest in northwestern Prince Edward Island and relatively low in the areas closest to Pomquet Harbour. We believe that green crab predation in the years leading up to our study may have strongly influenced the population structure of soft-shell clams in Pomquet Harbour. Both Glude (1955) and Welch (1968) report that green crabs effectively removed young-of-the-year soft-shell clams from affected beds. Reproductive output peaks late in life for soft-shell clams (Brousseau 1978), with larger clams providing most of the reproductive effort. In Pomquet Harbour, when the older cohorts senesce or die, larval supply to the bed will drastically decline.

Cage Artifacts

In any study involving the placement of structures on a mudflat, there is the potential for a variety of confounding physical and biologic effects (Hulberg & Oliver 1980). In this study, there was no significant difference in organic content between treatments, no noticeable scouring or deposition of sediment within the cages, and no post-experiment differences in sediment particle size distribution. The cages experienced little fouling and drift algal accumulation was minimal. These results suggest that cage-induced physical artifacts were minimized in this experiment.

Refuge and feeding by small epibenthic predators within cages is another possible confounding factor, and these types of organisms could have caused some of the mortality we observed in small soft-shell clams. We did not observe any such predators during biweekly checks or during the final sampling of the cages, however organisms such as small mummichogs (*Fundulus heteroclitus* Say), sand shrimp (*Crangon septemspinosa* Say), and small green and rock crab (*Cancer irroratus* Say) could have entered the cages at high tide, and exited prior to low tide. There are, however, several reasons why we feel that any impact of such predators on the experimental results was negligible. Mummichogs are very stout fish, and the 1-cm mesh-size of the cages would preclude fish larger than approximately 50 mm in length. Smaller fish could have preyed upon newly settled soft-shell clams in cages, but this

length is at the smaller range of fish reported to be effective predators on juvenile soft-shell clams (MacKenzie & McLaughlin 2000). We observed very few sand shrimp or rock crab at the site at any time. Finally, if predators such as these had removed small soft-shell clams, one would expect that they would remove similar numbers from all cages. If anything, the only bias one might expect would be for predators to avoid cages with green crabs, thereby making it more difficult to demonstrate a significant effect in green crab enclosure cages.

Clearly the confinement of the crabs in the D1 and D2 cages contributed to the crab mortality that occurred. The bulk (19 of 21) of the mortalities took place in the 20 days prior to the end of the experiment, from August 3 to August 23, 2001. Two crabs died in the D1 cages, in the absence of other crabs, suggesting the combination of starvation and the high daytime temperatures during this period could have contributed to the mortality. Cannibalism was likely a factor in the higher mortality observed in the D2 cages.

Aquaculture Implications

Our results suggest that soft-shell clam aquaculture operations in the southern Gulf of St. Lawrence should protect small soft-shell clams until they reach an appropriate size and depth refuge whereby they cannot be attacked by green crabs. If green crabs are allowed to prey freely on soft-shell clam beds, they will probably decimate small clam stocks and eventually cause steep population declines. Because adult soft-shell clams seem to have a depth refuge from predation, the effects of a decline of small clams may not be noticed until well after the onset of the green crab invasion, when the older, stronger year classes start dying off and are not replaced. Recreational or commercial harvesters only retain large clams, and may not immediately notice a reduction in numbers of small clams. Excluding green crabs by fencing is an effective mechanism for preservation of small soft-shell clams (Glude 1955, Beal & Kraus 2002). With the current expansion of green crabs into areas of heavy bivalve aquaculture, such a precaution may be needed to preserve harvested populations.

IN SITU AQUACULTURE PROTOCOL FOR TWO TROPICAL PECTINIDS, *BRACTECHLAMYS VEXILLUM* (REEVE 1853) AND *MIMACHLAMYS GLORIOSA* (REEVE 1853): SPAT COLLECTION, REARING, GROWTH AND MORTALITY

LAURENT WANTIEZ¹* AND PIERRE THOLLOT²

¹L'ERREM, University of New Caledonia, BP 4477, 98847 Noumea cedex, New Caledonia; ²deceased

ABSTRACT The aim of this study is to propose an *in situ* aquaculture protocol, including spat collecting and rearing, for two tropical species of Pectinids (*Bractechlamys vexillum* and *Mimachlamys gloriosa*). Spat were collected using small mesh bags (80 × 40 cm) filled with used fishing nets and fixed on lines 1.5 and 2.5 m above the sea bottom. The collecting lines were set above natural stocks during 2 months in 2 locations, and surveyed every 2 weeks. On average, 118 *Bractechlamys vexillum* (mean size 8.08 mm) and 132 *Mimachlamys gloriosa* (mean size 10.17 mm) were collected in each bag. The height of the bags above the sea bottom did not affect the collecting yield or the mean size of juveniles with either species. Predation was not directly evaluated in the bags but regular visual observations showed that it remained anecdotic during the 2-month collecting period. After 2 months, the juveniles were transferred to Japanese lantern nets (1.5 × 0.4 m) for rearing, each lantern containing ten levels. Lanterns were deployed in 2 locations and surveyed every 2 weeks for a period of 18 months. Two initial densities (400 individuals/m² and 800 individuals/m²) were studied for each species. Growth (Von bertalanffy model) of the two species was not affected by the tray position in the lantern. Density did not affect significantly K parameter but specimens reached a larger size in the low-density lantern. Growth of *Bractechlamys vexillum* was related to the site (K varied between 0.073 and 0.088 per week; H_∞ varied between 45.5 and 42.3 mm), with a lower K value but a bigger size in Baie des Citrons². Growth of *Mimachlamys gloriosa* was not linked to the site (K = 0.066 per week, H_∞ = 57 mm). *Bractechlamys vexillum* and *Mimachlamys gloriosa* were characterized by significant variations in mortality rates (20% to 70%) after 18 months of rearing. The influence of density was less conclusive. *Bractechlamys vexillum* displayed a higher mortality in the low-density lanterns and *Mimachlamys gloriosa* a lower mortality in low-density lanterns. The site had a similar effect on mortality rates for both species, with higher mortality in Baie des Citrons². Spat transfer losses only affected *Bractechlamys vexillum*. Diseases and biologic traits also affected the populations and mortality rates were variable between levels. Mortality models gave lower Z estimates for reared populations (0.16–0.43 per year for *Bractechlamys vexillum* and 0.16–0.55 per year for *Mimachlamys gloriosa*) than for natural populations. In conclusion, *in situ* aquaculture of the studied species is feasible and optimized protocols are proposed for spat collecting and rearing. Commercial size is reached after 12 months of rearing (43.2 mm for *Bractechlamys vexillum* and 54.8 mm for *Mimachlamys gloriosa*) with survivorship of 66% to 85% for *Bractechlamys vexillum*, and 58% to 86% for *Mimachlamys gloriosa* depending on density and site.

INTRODUCTION

Tropical pectinids are common in the New Caledonian lagoon (Lefort 1991). Six species have a commercial value and constitute exploitable stocks (Lefort 1991). However, the use of bottom trawled fishing devices (dredges and trawls) is forbidden by the Southern Province Authorities in all of the lagoon area because of their destructive impact on sea bottom habitats (Hutchings 1990). Because there is a demand for these shellfish on the local market, a temporary authorization was given to a commercial fisherman to collect pectinids using scuba diving gear between 1993 and 1995. This authorization was not renewed and today these stocks can only be exploited by snorkeling. Because this technique is laborious, has limited efficiency, and gives low collecting yields, it is only anecdotal and the resource is not exploited. A possible way of exploiting these organisms, which uses neither destructive fishing gear nor scuba diving, is to develop a simple *in situ* aquaculture protocol.

The aim of this study is to propose an *in situ* aquaculture protocol for two tropical pectinids, *Bractechlamys vexillum* (Reeve 1853) and *Mimachlamys gloriosa* (Reeve 1853). This protocol includes spat collection and juvenile rearing up to commercial size. Site selection, technical design, and methodology are described in

the present article. Spat availability and juvenile growth and mortality have been studied in relation to site characteristics and rearing density.

MATERIALS AND METHODS

Species studied

Two pectinid species were selected for this study, *Bractechlamys vexillum* (Reeve 1853) and *Mimachlamys gloriosa* (Reeve 1853). These species, which are of commercial interest, are the most common species in the South West lagoon of New Caledonia (Lefort 1991). *Bractechlamys vexillum* is a mobile species, which lives exclusively on soft-bottoms and concentrates in hollows, under *Halimeda* algae or close to small coral heads or sponges (Chauvet 2000). *Mimachlamys gloriosa* lives fixed on algae (*Avrainvillea nigricans*, *Halimeda cylindracea*), antipatharia (*Cirrhipathes*) or on hard substrate. Spawning of these species occurs all year long with more intensity in summer than in winter (Lefort & Clavier 1992), but the spat collecting yield is higher in winter (Chauvet 2000). Douchement and Chauvet (1994) and Chauvet (2000) showed that it was easily possible to collect wild spat for these two species.

Spat collecting

To successfully collect spat, the sites selected must be located near natural stocks with mature individuals (Douchement & Chau-

The Southern Province of New Caledonia Department of Living Resources funded this study.

vet 1994). Two sites located in bays near Nouméa (New Caledonia) were selected for spat collection, Nouville1 and Baie des Citrons1. Prior to the deployment of the collectors, the local pectinid populations were sampled in both sites. Nouville1, depth 11–13 m, has a muddy-sand bottom with some rocks, and is colonized by a typical "lagoon grey bottom" community (as defined by Richer de Forges et al. 1987) with algae (i.e. *Caulerpa*, *Halimeda*, *Sargassum*, *Udotea*), sponge, free-living corals (i.e. *Cyloseris cyclolites*, *Heteropsammia machelini*, *Trachiphyllia geofroyi*), gastropods (i.e. *Strombus luhuanus*) and holothurians (i.e. *Holothuria edulis*, *H. scabra*, *Stichopus variegatus*). *Mimachlamys gloriosa* was the more abundant of the two pectinids (70%) on this site, with individuals fixed upon *Halimeda*, sponges or hard substrate (shells fragments and dead corals). Baie des Citrons1, depth 11 m, has a uniform muddy-sand substrate, colonized by a "lagoon grey bottom" community quite similar to Nouville1. However, *Bractechlamys vexillum* was, by far, the more abundant of the two pectinids on this site (more than 90%), with individuals being partly buried in the sand or laying on the bottom.

Spat collecting devices were bags (80 × 40 cm) made of 50% agricultural shadowing curtain and filled with 6–8 m² of used nylon fishing nets of 3–6 cm square mesh size. The agricultural curtain has a 6 mm square mesh size, which allows the larvae to penetrate into the bag and protect the juveniles from external predators. Each collecting structure was made of two devices fixed onto a vertical rope, 1.5 m and 2.5 m above the bottom (Fig. 1). Ten collecting structures were set at each site, with nine of them surrounding a central one, each structure being at least 20 m apart. This design was adopted to optimize spat collection without knowledge of local current patterns. The collecting structures were set in August, which is the most favorable season according to Douchement and Chauvet (1994). They were controlled and fouling was removed from external bags twice a month. After 2 months, the juveniles were detached from the collectors and transferred to the rearing structures, as recommended by Douchement and Chauvet (1994). This collecting schedule is satisfactory to collect juveniles large enough for the rearing structure but not long enough for predators to develop inside the collecting bags and

consume the juveniles. Each juvenile transferred to the rearing structure was measured (shell height) to the nearest millimeter.

Rearing

The environmental characteristics of the rearing sites must be compatible with the growth of pectinids. Two rearing sites were selected, Nouville2 and Baie des Citrons2. Nouville2 is a lagoonal site, depth 20 m, and has a fine-sand bottom with a thin muddy layer on top. No algae lived on the bottom and epigeal macrobenthos was scarce, with only a few *Holothuria leucospilota*. Baie des Citrons2 is located in a coastal bay, depth 11 m, and has a muddy-sand bottom and was colonized by a "lagoon grey bottom" community quite similar to Baie des Citrons1.

Juveniles were grown in Japanese lantern nets (height 1.5 m). Each lantern was made of 10 trays (40 cm diameter) linked by three ropes resistant to heavy weight and protected by a net of 5 cm square mesh size. The trays were 15 cm apart. The protecting net allowed water and nutritive particles to penetrate to ensure the growth of pectinids, and prevent external predators from reaching the juveniles. This is a standard rearing technique widely used to grow similar species throughout the world (Imai 1980, Buestel et al. 1982, Dupony 1983, Lucien-Brun & Lachaux 1983, Lovatelli 1987, Barnabé 1989, Dao 1989, Doumenge 1989, among others). Four lanterns were fixed to a rearing structure at each site (Fig. 2).

At each site, one low and one high-density lantern were set for each species to test two initial rearing densities: 400 individuals/m² (50 individuals per tray) and 800 individuals/m² (100 individuals per tray). The lanterns were checked every 2 weeks, fouling was removed if necessary, as all potential predators (mainly crabs), which recruited in the lantern, and dead pectinids. All living specimens were counted and shell height was measured every month for 18 months. Handling operations were restricted as much as possible to avoid physiologic stress, individuals being always kept in water when removed from the trays.

Data analysis

A three way Anova and *post hoc* tests (Sokal & Rohlf 1981) were used to test the impact of species, site and height above sea bottom on spat collecting yields.

A Von bertalanffy growth model (Sparre et al. 1989) was calculated for *Bractechlamys vexillum* and *Mimachlamys gloriosa*:

$$H_t = H_{\infty}(1 - e^{-K(t-t_0)})$$

Figure 1. Design of spat collecting devices.

Figure 2. Design of rearing structures.

where H_t shell height at age t (mm); H_∞ maximum shell height (mm); K curvature parameter (per week); t age (week); t_0 initial condition parameter. These parameters were estimated by the Gulland and Holt method (Sparre et al. 1989), using shell size increases between two successive samplings. Both growth parameters were derived from a linear regression:

$$\frac{\Delta H}{\Delta t} = KH_\infty - KH_t$$

where ΔH shell height increase between two samplings (mm); Δt time between two samplings (week). The initial condition parameter (t_0) was set to zero. K parameters were compared using the test for equality of slopes and unplanned comparisons among a set of regression coefficients (Sokal & Rohlf 1981).

Instantaneous and cumulated mortality rates (MI) were calculated between two sampling dates:

$$MI_{i+1} = \frac{N_i - N_{i+1}}{N_i}$$

where MI_{i+1} instantaneous mortality rate at $t = i+1$; N_i number of living specimens at $t = i$; N_{i+1} number of living specimens at $t = i+1$. Cumulated mortality rates were calculated from the beginning of the rearing phase:

$$MC_i = \frac{N_0 - N_i}{N_0}$$

where MC_i cumulated mortality at $t = i$; N_0 Initial number of specimens. A Mortality model was calculated:

$$N_t = N_0 e^{-Zt}$$

where N_t Number of living specimens at age t ; Z instantaneous rate of total mortality (per year). These parameters were estimated using a linear regression after logarithm transformation and compared using the test for equality of slopes and unplanned comparisons among a set of regression coefficients (Sokal & Rohlf 1981).

RESULTS

Spat collecting

The mean number of spat larger than 7 mm was 118 ± 38 specimens per bag for *Bractechlamys vexillum* and 132 ± 38 specimens per bag for *Mimachlamys gloriosa*, for both sites. A significant interaction occurred between site and species (Anova, $P < 0.01$), which did not allow us to test these two factors separately. This interaction was a result of significantly higher yields per collector in Nouville1 for *Bractechlamys vexillum* (Mann-Whitney test, $P < 0.05$, Table 1) in spite of the dominance of *Mimachlamys gloriosa* adult populations at this site. The opposite pattern was observed in Baie des Citrons1 with significantly higher yields per collector for *Mimachlamys gloriosa* (Mann-Whitney test, $P < 0.05$, Table 1) in spite of the dominance of *Bractechlamys vexillum* adult populations. The height of the collecting bag above the sea bottom had no significant effect on collecting yields (Anova, $P > 0.05$, Table 1). However, the general trend was higher collecting yields in the lower bag (Table 1). Regular visual observation during fouling removal and the absence of predators big enough to eat the spat inside the bags at the end of the collecting phase, showed that spat loss was negligible during the 2-month period of spat collecting.

The mean shell height of collected juveniles was 8.08 mm for

Bractechlamys vexillum (max 14 mm) and 10.17 mm for *Mimachlamys gloriosa* (max 17 mm). A significant interaction occurred between site and species (Anova, $P < 0.01$), which did not allow us to test these two factors separately. This interaction was a result of *Mimachlamys gloriosa* having a significantly larger size on both sites (t -Student test, $P < 0.001$, Table 2) and specimens having a larger shell height in Nouville1 than in Baie des Citrons1 for each species (t -Student test, $P < 0.01$, Table 2). The height of the collecting bag above the sea bottom had no significant effect on juvenile size (Anova, $P > 0.05$, Table 2).

The size frequency distributions of juveniles bigger than 7 mm, are similar for both species (Fig. 3). Distributions were unimodal with a left skewness due to minimum size selection (Fig. 3). Size variation among specimens was low for both species (CV lower than 12%). The two most important size classes included 57–79% of the specimens, with the exception of *Mimachlamys gloriosa* in Nouville2 where these two classes only included 42% of the specimens (Fig. 3). However, the size frequency distribution differed slightly between sites (Fig. 3), with a 1-mm lag in Baie des Citrons2 compared with Nouville2.

Rearing and growth of *Bractechlamys vexillum*

Bractechlamys vexillum size increased regularly on all trays to reach a mean size per tray between 38 and 53 mm after 18 months.

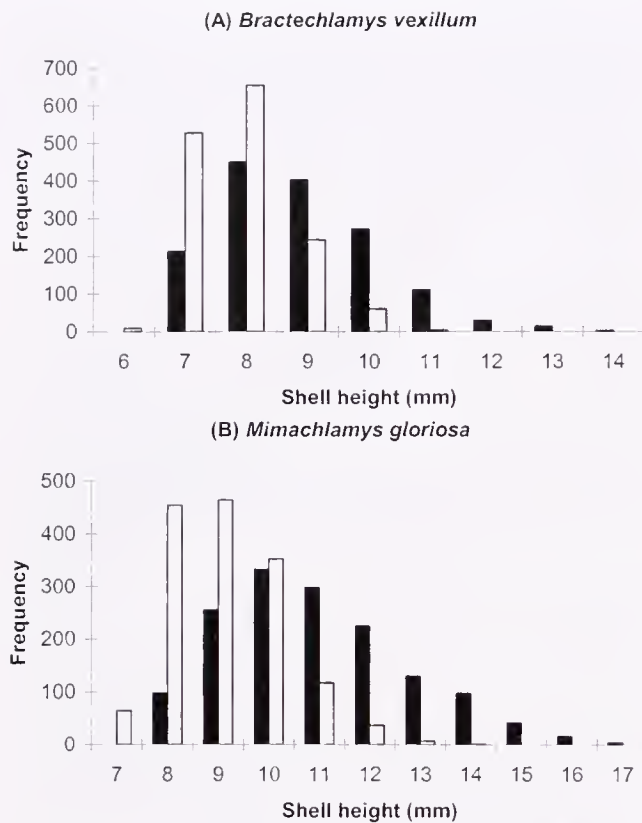

Figure 3. Size frequency distribution of the collected juveniles per species (A and B) and per site (black: Nouville1; white: Baie des Citrons1).

Daily increase rates were higher at the beginning of the rearing period (maximum 0.34 mm/day) and decreased rapidly to become very low after 200–250 rearing days (< 0.05 mm/day). A growth model was calculated for each tray to test the effect of tray position on growth. The theoretical maximum shell height (H_{∞}) cannot be statistically compared, and no clear pattern was observed with tray position (Table 3). Curvature parameters, which determine how fast the specimens approach maximum size, were compared among trays of each lantern (Table 3). Differences were not significant for low-density lanterns (comparison of regression coefficients, $P > 0.05$). Significant differences occurred in high-density lanterns (unplanned comparison of regression coefficients, $P < 0.05$, Table 3). However, the link between *Bractechlamys vexillum* growth and tray position was not interpretable. Consequently, all trays were pooled to test the effect of density on growth.

Similar patterns were observed for shell height and daily growth rates (Fig. 4). However, *Bractechlamys vexillum* reached a larger size in low-density lanterns (47.4 mm in Baie des Citrons2 and 43.6 mm in Nouville2) than in high-density ones (42.9 mm in Baie des Citrons2 and 40.6 mm in Nouville) (Student test, $P < 0.001$). A growth model was calculated for each lantern to test the effect of density on growth (Table 3). H_{∞} was higher for low-density lanterns (47.9 mm in Baie des Citrons2 and 44.0 mm in Nouville2) than for high-density ones (43.2 mm in Baie des Citrons2 and 40.6 mm in Nouville2). However, there was no significant difference between curvature parameters of low and high-density lanterns (comparison of regression coefficients, $P > 0.05$). Consequently, low and high-density lanterns were pooled to test the effect of site on growth.

Trays are ranked per K values. K, curvature parameter (per week); H_{∞} , Maximum shell height (mm).

Vertical lines regroup K values not significantly different (unplanned comparison of regression coefficients, $P > 0.05$).

Similar patterns were observed for shell height and daily increase rates at both sites, despite a larger size in Baie des Citrons2 (44.5 mm) than in Nouville2 (41.3 mm) (Student test, $P < 0.001$). A growth model was calculated for each site (Fig. 4). Baie des Citrons2 was characterized by a significantly lower growth rate (comparison of regression coefficients, $P < 0.05$) and a larger maximum size ($K = 0.073$ per week, $H_{\infty} = 45.5$ mm) than Nouville2 ($K = 0.088$ per week, $H_{\infty} = 42.3$ mm) (see Fig. 4). Growth was similar on both sites during the initial growth phase (up to 35 mm) and differed after 6 months of rearing (Fig. 4).

Rearing and growth of *Mimachlamys gloriosa*

Mimachlamys gloriosa size increased regularly on all trays to reach a mean size per tray of between 51 and 60 mm after 18 months. Daily increase rates decreased rapidly and became very low after 250 to 300 rearing days (< 0.05 mm/day). A growth model was calculated for each tray to test the effect of tray position on growth. The theoretical maximum shell height cannot be statistically compared, and no clear pattern was observed with tray position (Table 4). Curvature parameters were compared among trays of each lantern (Table 4). The differences were not significant (comparison of regression coefficients, $P > 0.05$). Tray posi-

tion had no significant effect on growth. Consequently, all trays were pooled to test the effect of density on growth.

Similar patterns were observed for shell height and daily growth rates (Fig. 5). However *Mimachlamys gloriosa* reached a larger size in low-density lanterns (59.1 mm in Baie des Citrons2 and 55.2 mm in Nouville2) than in high-density ones (53.9 mm in Baie des Citrons2 and 54.4 mm in Nouville2) (Student test, $P < 0.001$ in Baie des Citrons2 and $P < 0.05$ in Nouville2). A growth model was calculated for each lantern to test the effect of density on growth (see Table 4). H_{∞} was higher for low-density lanterns (60.7 mm in Baie des Citrons2 and 56.7 mm in Nouville2) than for high-density ones (54.1 mm in Baie des Citrons2 and 54.5 mm in Nouville2). However, there was no significant difference between curvature parameters of low and high-density lanterns (comparison of regression coefficients, $P > 0.05$). Consequently, low and high-density lanterns were pooled to test the effect of site on growth.

Similar patterns were observed for shell height and daily growth rates, and *Mimachlamys gloriosa* reached the same mean size (57 mm) on both sites. A growth model was calculated for each site (Fig. 5). Growth parameters calculated on the 2 sites were very close ($K = 0.069$ per week $H_{\infty} = 56.2$ mm in Nouville2 and $K = 0.063$ per week $H_{\infty} = 57.4$ mm in Baie des Citrons2). Curvature parameters were not significantly different (comparison of regression coefficients, $P > 0.05$). Growth was similar on both sites during all the rearing period (see Fig. 5). Consequently, a

global Von bertalanffy growth model was calculated: $K = 0.066$ per week and $H_{\infty} = 57$ mm.

Mortality of *Bractechlamys vexillum*

Instantaneous mortality rates (MI) of *Bractechlamys vexillum* per tray were so heterogeneous and variable that the mortality model was only applicable for 29 of the 40 trays (Table 5). Instantaneous rates of total mortality (Z) calculated for these trays were significantly different (unplanned comparison of regression coefficients, $P < 0.05$) (Table 5). However, the effect of tray position was not interpretable (Table 5). Consequently, data from each tray of a lantern were pooled to test the effect of density and site on mortality.

Two periods were characterized by high mortality rates (Fig. 6). The first one took place just after the transfer of juveniles from collecting devices, particularly on low-density lanterns (Fig. 6). After this first period, the instantaneous mortality rates decreased greatly and varied between 0 and 10%. These rates increased at the end of the rearing period, particularly in the Nouville2 low-density lantern and the Baie des Citrons2 high-density lantern (Fig. 6). Punctual high mortality rates were also observed on a few trays, between 150 and 250 rearing days. Cumulated mortality rates increased regularly (Fig. 6). In Nouville2, the final cumulated mor-

Figure 5. Shell height (▲), daily increase rates (●) and von Bertalanffy growth model (thick line) of *Mimachlamys gloriosa* in Nouville2 (A) and Baie des Citrons2 (B). Continuous lines represent high-density lantern and broken lines represent low-density lantern.

tality rate was higher in the low-density lantern (58%) than in the high-density one (21%) (Fig. 6). Density had a significant effect on the modeled mortality (Fig. 7). The instantaneous rate of total mortality (Z) was significantly higher in low-density lanterns for each site (comparison of regression coefficients, $P < 0.05$) (Table 5; Fig. 7). Consequently, the effect of site was tested separately for each density level.

For the low-density lanterns, instantaneous rates of total mortality (Z) were not significantly different between sites (comparison of regression coefficients, $P > 0.05$, Table 5, Fig. 7). Conversely, differences were significant for high-density lanterns with lower rates in Nouville2 (comparison of regression coefficients, $P < 0.05$, Table 5, Fig. 7). Despite significant effects of rearing density and site on mortality of *Bracteacclamys vexillum*, mortality models were quite similar for the 2 sites and density levels, with the exception of the high-density lantern in Nouville2 characterized by low mortality rates (Fig. 7).

Mortality of *Mimachlamys gloriosa*

Instantaneous mortality rates (M) of *Mimachlamys gloriosa* satisfied the mortality model for all trays. Significant differences in instantaneous rates of total mortality (Z) occurred between trays (comparison of regression coefficients, $P < 0.05$, Table 6). Z was significantly higher in tray n°1 of the high-density lantern in Baie des Citrons2, and high values characterized n°1 tray of the other lanterns (unplanned comparison of regression coefficients, $P <$

0.05, Table 6). The variations in mortality on the other trays were not linked to tray position (Table 6). Data from all trays of each lantern were pooled to test the effect of density on mortality.

No significant mortality was observed after the transfer of juveniles and instantaneous mortality rates (MI) were low at the beginning of the rearing period (Fig. 8). These rates increased after 250 to 300 rearing days and were higher at the end of the rearing period. At the end of the rearing period, cumulated mortality rates were close to 50% for low-density lanterns and 70% for high-density lanterns in Baie des Citrons2, and reached 29% for low-density lanterns and 39% for high-density lanterns in Nouville2 (see Fig. 8). Density had a significant effect on modeled mortality. Instantaneous rates of total mortality (Z) were higher on high-density lanterns (comparison of regression coefficients, $P < 0.05$, Table 6, Fig. 9). Consequently, the effect of site was tested separately for each density level.

Instantaneous rates of total mortality (Z) were significantly higher in Baie des Citrons2 than in Nouville2 for each density level (comparison of regression coefficients, $P < 0.05$, Table 6)

indicating a better survival in Nouville2 than in Baie des Citrons2 (Fig. 9).

DISCUSSION

Spat collecting

During this study nearly all the juveniles that recruited in the collecting bags were *Bractechlamys vexillum* and *Mimachlamys*

Figure 9. Modeled survivorship of *Mimachlamys gloriosa* by density and site. Model parameters are given in Table 6. Continuous lines represent high-density lantern and broken lines represent low-density lantern.

gloriosa, as observed by Chauvet (2000). Spat collecting yields were similar to those reported by Douchement and Chauvet (1994) in Baie des Citrons (114.7 juveniles of more than 7 mm per bag) for *Mimachlamys gloriosa*. Conversely, these authors reported lower yields for *Bractechlamys vexillum* (21.6 juvenile of more than 7 mm per bag in Baie des Citrons) than in this study. These differences probably reflect inter-annual variations in recruitment, as both studies were completed during the same season, which, according to Chauvet (2000) is the best recruitment season. This author also reported highly variable collecting yields per bag as in this study.

The results of this indicate an interaction between site and collected species. Such interaction was also observed by Douchement and Chauvet (1994). The presence of an adult population at a collecting site increase chances of spat recruitment but not necessarily high collecting yields. Other significant factors also affect collecting yields. Current patterns are important for invertebrate larval dispersal and recruitment even for species with a short plankton larval phase (Shanks et al. 2003), such as the common Pectinids in the New Caledonian lagoon (up to 6 days for *Bractechlamys vexillum* and 15 days for *Mimachlamys gloriosa*, Lefort & Clavier 1992). These patterns probably had a significant effect, on the higher collecting yields of *Bractechlamys vexillum* at Nouville1, despite the higher abundance of *Mimachlamys gloriosa*, and the opposite pattern observed at Baie des Citrons1. Douchement and Chauvet (1994) observed an opposite pattern than in this study, with collecting yields being nearly 3 times higher for *Mimachlamys gloriosa* than *Bractechlamys vexillum* in Baie des Citrons. Their results indicate that other factors may intervene.

Chauvet (2000) reported low collecting yields near the sea bottom, higher yields up to 2.5–3 m above the bottom and decreasing yields above 3 m. These results are similar to those for temperate scallop species (Brand et al. 1980, among others). During this study, collectors were installed in a narrow range, as recommended by Douchement and Chauvet (1994), that explained the absence of significant effect of this factor on collecting yields.

The approach of limiting the collecting phase to 2 months successfully prevented the impact of predators in the bags. This impact is known to be significant for temperate species when the collecting period is too long (Brand et al. 1980; Thouzeau 1991). During this study, crabs had recruited in the bags but they did not have time to grow large enough to deplete the juvenile populations of Pectinids.

The duration of the collecting phase was long enough to obtain juveniles at a size suitable to be transferred to the subsequent culture phase (size >7 mm) for the two species studied. Maximum juvenile sizes were similar to those of Douchement and Chauvet (1994) after similar collecting phases for both species. Mean sizes were also similar for *Bractechlamys vexillum* but the mean size of *Mimachlamys gloriosa* was smaller (<9 mm) in the study of Douchement and Chauvet (1994). Post recruitment growth was faster for *Mimachlamys gloriosa* (10.6 mm/month) than for *Bractechlamys vexillum* (8.6 mm/month) (Chauvet 2000), which explained the differences observed in the mean size of juveniles between the two species at the end of the collecting phase. The mean size of juveniles was also larger in Nouville1 than in Baie des Citrons1 during this study because of the sampling schedule. Bags located in Nouville1 were collected 5 days after those in Baie des Citrons1. During these 5 days juveniles continued to grow and the differences in mean sizes corresponded to the growth rates

given by Chauvet (2000). This is confirmed by the differences in size frequency distributions between sites for both species. An extended recruitment phase could explain the difference in size frequency distribution observed in Nouville1 for *Mimachlamys gloriosa* compared with the other species and sites. Douchement and Chauvet (1994) and this study both reported size frequency distribution for *Mimachlamys gloriosa* juveniles of more than 7 mm was unimodal with a left skewness.

Growth of *Bractechlamys vexillum*

No significant links were observed between tray position and growth of *Bractechlamys vexillum*. The significant differences of K values observed in the high-density lanterns were probably due to variable individual growth and mortality within the trays. Conversely, growth was probably linked to density. K values were not statistically different but size at the end of the rearing period and H_{∞} values were higher in the low-density lanterns. Parsons and Dadswell (1992) found an inverse relationship between growth and stocking density for a temperate scallop species (*Placopecten magellanicus*), and Maeda-Martinez et al. (1997) observed lower growth rates at the highest densities at each of the three culture stages of a tropical scallop (*Argopecten ventricosus*). Limited trophic resources in the high-density lanterns when specimens attain larger size, could explain these differences during the second part of the rearing period (after 200 rearing days). Site had a significant effect on growth. K was lower but specimens probably reached larger sizes in Baie des Citrons2. It is possible that a higher productivity at this site (coastal bay where terrestrial runoff may be important) minimized the impact of limited trophic resources. It was also observed during maintenance operations that fouling was more abundant and developed more quickly in Baie des Citrons2 than Nouville2. Parameters of the Von bertalanffy growth model in experimental rearing structures ($K > 0.07$ per week and $H_{\infty} < 42$ mm) were characteristic of a higher initial growth rate but a lower maximum size than the estimations of Lefort and Clavier (1992) for natural populations in the same lagoon ($K = 0.036$ per week and $H_{\infty} = 47.4$ mm). Two factors could explain why growth in artificial structures is not optimal: limitation of trophic resources and a mortality affecting the bigger specimens at the end of the rearing period. The influence of fouling on growth is known to be significant (Lodeiros & Himmelman 2000). This effect should be limited during this study because fouling was regularly removed. Size differences between specimens after 12 and 18 months were very low (<2 mm) in all the lanterns.

Growth of *Mimachlamys gloriosa*

Tray position, density and site had no significant effect on K parameter of Von bertalanffy growth model for *Mimachlamys gloriosa*. However, density probably had a limited effect on growth because the specimens reached a larger size and H_{∞} was higher in the low-density lanterns. Parameters of the Von bertalanffy growth model in experimental rearing structures ($K = 0.066$ and $H_{\infty} = 57$ mm) were characteristic of a higher initial growth rate but a lower maximum size than the estimations of Lefort and Clavier (1992) for natural populations in the same lagoon ($K = 0.019$ per week and $H_{\infty} = 73.9$ mm). The growth of this species was probably not optimal in the artificial rearing structure at the densities tested. The duration of the rearing phase was sufficient for specimens to reach the maximum sizes observed in natural populations. However, the

lower mean size reached in experimental conditions was probably due to limited trophic resources in both sites during the second part of the rearing period. Because *Mimachlamys gloriosa* is a larger species than *Bractechlamys vexillum* it probably had higher feeding demand. Therefore, space between trays and water circulation in the lantern may have been too limited when specimens reached a certain size. Moreover, competitive sponges colonized the pectinids' shell. Another significant factor affecting maximum size is mortality, which affected the larger specimens at the end of the rearing period. Size differences between specimens after 12 and 18 months were very low (< 2 mm) in all the lanterns.

Mortality of *Bractechlamys vexillum*

Mortality of *Bractechlamys vexillum* in the rearing structures was highly variable. The high mortality rates after the transfer of juveniles were probably related to biologic stress during handling procedures and death of smaller specimens trapped between the tray structures. Well-developed gonads were observed after 150–250 rearing days corresponding to sexual maturity (Lefort & Clavier 1992). This period was also characterized by punctual high mortality rates related to the first reproduction event, particularly in Baie des Citrons². Lodeiros and Himmelman (2000) reported a decreased survival in the period during and just after spawning for a tropical scallop (*Envula ziczac*), possibly coincident with physiologic stress from spawning. After reaching sexual maturity this species is characterized by continuous reproduction. Therefore, the impact on mortality was not detectable. Other punctual mortality events were related to predation by mollusks (Cymatiidae) or crabs (*Portunus*) in some trays and the possible effect of pathogens. The significant mortality at the end of the rearing period was probably due to the senescence of the population. Density had a significant effect on the mortality of *Bractechlamys vexillum*. A higher mortality (Z and cumulated mortality) occurred in the low-density lanterns at each site. Site only had a significant effect on high-density lanterns. The action of pathogens in low-density lanterns, highly variable density results, densities tested below a threshold in which significant differences would be detected, or the action of other uncontrolled factors could explain this unexpected result. However it was not possible to identify these factors from the results of this study.

Z values calculated during this study ($Z = 0.16\text{--}0.43$ per year) were lower than the values calculated by Lefort (1991) and Lefort and Clavier (1992) (0.86 per year) for natural populations in the same lagoon. This result is consistent because of the limited predation in artificial rearing conditions, because a net protects specimens. The only predators found in the lanterns during the rearing phase were mollusks (*Septa tabulata*) and Portunid crabs (*Portunus*). These predators recruited in the lanterns and had begun to grow before being removed during maintenance operations.

Mortality of *Mimachlamys gloriosa*

Mortality rates were variable and Z coefficients were significantly different between trays. Z was higher in trays located at the bottom of the lanterns, in particular in the Baie des Citrons² high-density lantern. However, mortality rates displayed no gradient from top to bottom. *Mimachlamys gloriosa*, unlike *Bractechlamys vexillum*, was not affected by high mortality rates after the transfer of juveniles. The transferred juveniles were larger and did not get trapped between trays. Moreover, this species is byssally attached which may have contributed to lower mortality by avoiding en-

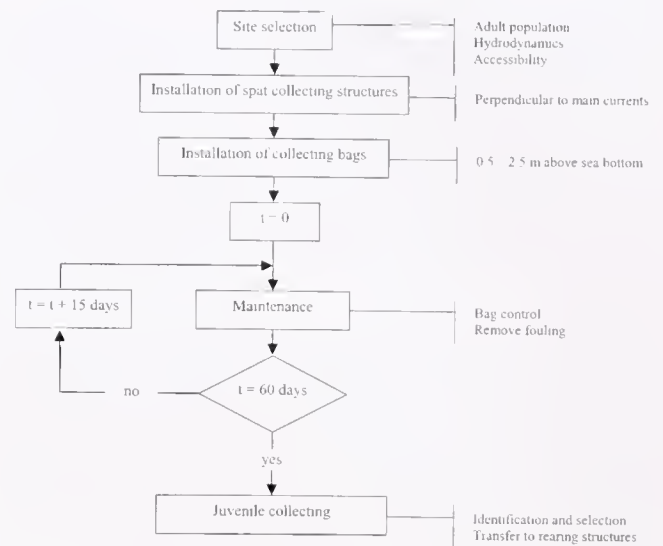

Figure 10. Spat collecting protocol for *Bractechlamys vexillum* and *Mimachlamys gloriosa*

trapment and imbrications. The mortality probably increased at the end of the rearing period because of the senescence of the population. Density and site had significant effects on the mortality of *Mimachlamys gloriosa*. Mortality was higher in the high-density lanterns, this pattern being the opposite of *Bractechlamys vexillum*. Competition for food and space could explain this result. However, Parsons and Dadswell (1992) found that survival of a temperate scallop species (*Placopecten magellanicus*) was not influenced by density. When the specimens grow and reach sexual maturity, food resources can become too low at a time when more energy is necessary for reproduction. Lodeiros and Himmelman (2000) reported a decreased survival in the period during and just after spawning for a tropical scallop (*Envula ziczac*), possibly coincident with physiologic stress from spawning and low phytoplankton abundance and high temperatures. Consequently, specimens weaken and become more sensitive to pathogens and toxic phytoplankton. This phenomenon was more significant in Baie des

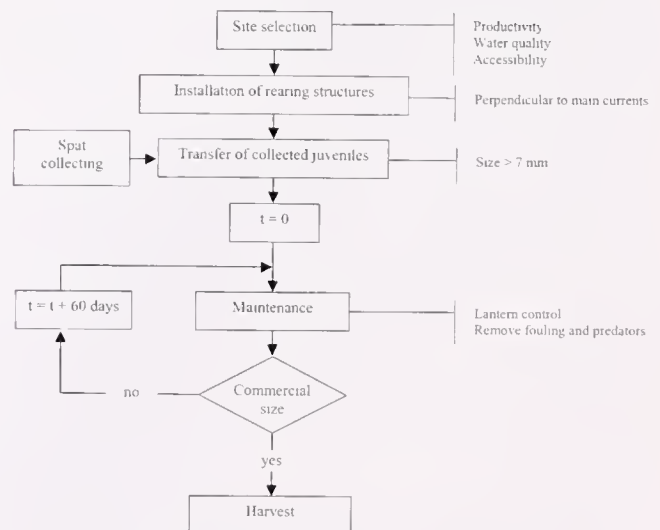

Figure 11. Optimized juvenile rearing protocol for *Bractechlamys vexillum* and *Mimachlamys gloriosa*.

Citrons2, where anthropogenic impact is more important (sewage and beach) and phytoplankton blooms were observed.

Z values calculated for this study ($Z = 0.16\text{--}0.55$ per year) were close to those given by Lefort (1991) and Lefort and Clavier (1992) (0.42 per year). However, these values were lower in all lanterns, except that at Baie des Citrons2. Predation was reduced in the rearing structure because of the protection of the net and the removal of predators during maintenance procedures.

Aquaculture protocol optimization

The spat-collecting phase was successful and a protocol can be proposed (Fig. 10). Adult populations should be present at the collecting site to optimize collecting yields. The rearing phase was also successful but could be optimized. Both species reached a commercial size within 12 months. Growth rates decreased and mortality rates increased after 12 months. With a rearing phase limited to 12 months the size of *Bractechlamys vexillum* should vary between 41.9 and 44.5 mm depending on density versus 42.2

to 45.3 mm for an 18-month rearing period. However, survivorship would increase to 66% to 85% (12 mo period) versus 55% to 80% (18 mo period). For *Mimachlamys gloriosa* size would decrease from 56.3 mm (18 mo period) to 54.8 mm (12 mo period) on average but survivorship should increase to 58% to 86% (12 mo period) versus 46% to 80% (18 mo period) depending on density. The rearing site must be located in a productive area where sea-water quality is suitable for the species. High-density lanterns bring better yields than low densities and should be preferred for a 12-month rearing period. An optimized rearing protocol is presented in Figure 11.

ACKNOWLEDGMENT

The authors thank Richard Farman and François Devineck for supporting this study and the crews of the Southern Province patrol boats, particularly Gérard Charmean, Michel Blanc and Christophe Gosset, for their technical assistance during the survey. The authors thank the anonymous referees for constructive comments on the manuscript.

ABSTRACT Coastal areas of southern Brazil are experiencing an intense development of bivalve farming, and the lion's paw scallop, *Nodipecten nodosus* (Linnaeus, 1758), is a promising aquaculture species. An important but poorly understood oceanographic feature described for the inner continental shelf of the southeastern Brazilian coast is the seasonal subsurface intrusion of cold and phytoplankton-rich South Atlantic Central Water (SACW) during summer–autumn. It was not clear, however, if these intrusions could affect near-shore coastal areas off Santa Catarina State, where aquaculture activities are now expanding, nor if they could affect growth and survival of bivalves under culture conditions. It was therefore hypothesized that intrusions of SACW with higher food levels and lower temperature would result in depth-related differences in environmental factors that would affect bivalve growth. One experiment was carried out in summer–early autumn (March–April 2001), a period of possible SACW intrusion in a coastal site, and a second experiment was carried out in late autumn–early winter (June–July 2001) when the water column would possibly be homogeneous. In both experiments, hatchery-produced postlarval *N. nodosus* (0.4 mm) were deployed in the sea-based nursery 12–15 days after settlement and retrieved 26–27 days later. Postlarvae were attached to Netlon collectors, placed inside nylon bags, and hung on a subsurface long-line at 4 and 12 m. The effects of deploying postlarvae at two densities (340 and 150 scallops/spat bag) were also investigated. Subsurface intrusions of cold and phytoplankton-rich SACW occurred at a near-shore (<0.5 km) coastal site in late summer–early autumn but not in late autumn–early winter. The influence of SACW resulted in oscillating temperatures (17.8–27.2°C) on a short time-scale and in high particulate inorganic matter (PIM), which reduced postlarval growth at 12 m compared with 4 m, but did not affect survival. When SACW was not present, there were no depth-related differences. Postlarvae cultured at high density displayed slightly smaller shell heights at both depths than postlarvae kept at low density but displayed similar survival, resulting in higher yields (no. spat/bag). The use of a subsurface long-line for deploying hatchery-produced postlarvae (0.4 mm) resulted in percentage retrievals of about 70–80%, regardless of treatment and season, values that are higher than in previous studies. There is a good potential for growing *N. nodosus* in sea-based nurseries in coastal areas of southern Brazil, and growth can be optimized by seasonally adjusting culture depth.

KEY WORDS: environmental factors, growth, *Nodipecten nodosus*, nursery culture, postlarvae, scallop, survival

INTRODUCTION

Coastal sheltered areas off Santa Catarina State, in southern Brazil, are currently experiencing an intense development of bivalve aquaculture, but the influence of environmental variability on bivalve growth and survival has only recently been addressed (Rupp 2003). As coastal embayments continue to be used, there will be a need in the near future to expand aquaculture activities to deeper areas farther from shore. It is therefore crucial to understand the influence of depth-related variability in environmental factors on growth and survivorship of bivalves to establish sustainable culture strategies. The lion's paw scallop, *Nodipecten nodosus* (Linnaeus, 1758), is a promising aquaculture species in Brazil, and an understanding of the influence of environmental factors on growth and survival are essential for the establishment of this new activity.

The South Brazil Bight (SBB) between Cabo Frio (23°S) and Cabo de Santa Marta (28.5°S) is one of the most economically and ecologically important regions on the Brazilian coast, but the effects of its oceanographic variability are still poorly understood (Brandini 1990, Campos et al. 1996, Borzone et al. 1999), and no previous studies have assessed the influence of spatial variability

of environmental factors on bivalve growth. An important and poorly understood oceanographic feature influencing the SBB is the seasonal subsurface intrusion of cold and phytoplankton-rich South Atlantic Central Water (SACW), which ascends the continental slope from deeper layers, influencing the shelf region (Matsuura 1986, Brandini 1990, Campos et al. 1996, Castro & Miranda 1998, Sunyé & Servain 1998). Except for coastal upwelling at the extreme limits of the SBB, SACW has previously been considered to influence mainly the middle and outer continental shelf, detected at distances greater than 30 km from shore (Castro & Miranda 1998). However, subsurface intrusions of SACW can influence inner shelf waters up to 15 m in a 38-m-deep station during summer (Borzone et al. 1999). This oceanographic feature may have an important influence on growth and reproduction of benthic invertebrates, but to date biological effects of SACW on marine bivalves have not been addressed. Furthermore, it is not known whether SACW can reach near-shore (<1 km) coastal areas off Santa Catarina State where aquaculture activities are now expanding, nor if these subsurface intrusions could affect growth and survival of cultured bivalves to such a degree as to be an important factor to be considered when establishing aquaculture sites and husbandry practices.

Whereas the influence of depth on growth of juvenile and adult scallops has extensively been studied in temperate and boreal regions (examples in Bricelj & Shumway 1991, Thompson & Mac-

*Corresponding author. E-mail rupp@epagri.rct-sc.br

Donald 1991), none of these studies were carried out in a subtropical environment, nor have they focused on the postlarval stage. Though some studies have reported slower growth near the surface (MacDonald & Bourne 1989, Román et al. 1999), growth usually decreases below a critical depth, as environmental conditions such as temperature, food availability, or turbidity often display a vertical gradient, reaching suboptimal levels in deeper waters (Leighton 1979, MacDonald & Thompson 1985, MacDonald & Bourne 1989, Côté et al. 1993, Emerson et al. 1994, Lodeiros et al. 1998, Grecian et al. 2000, Lodeiros & Himmelman 2000, Fréchette & Daigle 2002). In view of the environmental variability characteristic of waters off southern Brazil, it is possible that an unusual situation of high food level and low temperature below a crucial depth could influence growth of scallops in suspended culture close to shore.

The stocking density of bivalves within enclosures is an important variable to be considered in aquaculture, due to intraspecific competition for food and space. Density-dependent growth of juvenile and adult scallops cultured in lantern or pearl nets has been well documented (Duggan 1973, Ventilla 1982, Parsons & Dadswell 1992, Côté et al. 1993, Côté et al. 1994, Maeda-Martinez et al. 1997, Román et al. 1999), but few studies have focused on postlarval scallops within the size range examined in the current work, in which spat were attached to the collectors by byssal threads instead of lying on the floor of the culture nets (Grecian et al. 2000).

The main objective of the current study was to investigate the influences of environmental factors associated with depth on growth and percentage retrievals of postlarval *N. nodosus*. Experiments were carried out during a period when SACW could possibly influence the coastal site (experiment 1) (March–April) as well as when no influence of SACW was expected (experiment 2) (June–July). It was hypothesized that a cold and phytoplankton-rich water mass originating from SACW intrusions could reach the coastal aquaculture site in late summer, resulting in significant depth-related differences in growth of postlarval scallops above and below the thermocline. Conversely, in periods when the SACW is absent, growth should be similar at different depths. A second objective was to investigate the effects of stocking density on growth of postlarval scallops.

MATERIALS AND METHODS

Study Area

Experiments were undertaken off Porto Belo Point (Lat. 27°07'S; Long. 48°30.8'W), Santa Catarina State, Brazil (Fig. 1). A subsurface long-line, on which the main line was located 3 m below the surface, was deployed at a 15-m-deep site, 150 m from shore.

Spat Production

Experimental production of postlarval *N. nodosus* was undertaken at the Laboratory for the Culture of Marine Molluscs (LCMM-UFSC), Florianópolis, Santa Catarina State, Brazil. Two experimental spat productions were carried out in February and May 2001, using procedures described in Rupp et al. (2004). When larvae were competent to undergo settlement and metamorphosis, they were retained on a 140- μ m-mesh nytex screen, counted, and transferred to the experimental tanks. Settlement occurred in 200-L tanks, with pediveligers stocked at densities of 1.2 larvae mL⁻¹.

Japanese-type Netlon monofilament collectors of about 1.5-m long (averaging 105.2 g, SE = 1.2; n = 9), commonly used in scallop commercial operations, were used as substrate for settlement. During settlement, seawater (salinity = 33‰ to 34‰) was UV-irradiated and passed through a 1- μ m cartridge filter. Water was changed daily, and a food ration consisting of a mixture of *Isochrysis galbana* (T-iso), *Chaetoceros calcitrans*, and *C. muelleri* (2:2:1) in exponential growth phase was supplied daily in final concentrations ranging from 4×10^4 to 5×10^4 cells mL⁻¹. In the laboratory, water temperatures were 24–25°C and 21–22°C for experiments 1 and 2, respectively.

Experimental Approach

In experiment 1, carried out from mid-March to mid-April 2001 (late summer–early autumn), postlarval scallops were transferred to the field 12 days after settlement. The Netlon collectors were taken from the setting tanks, placed inside 1.5-mm-mesh nylon spat bags (1 collector/bag), and then transferred to the sea. The nylon spat bags were inserted into plastic bags filled with filtered seawater that were tightly closed and transported to the field site inside Styrofoam containers. Prior to deployment, four collectors per tank were sampled to estimate the initial number and size of postlarvae. Collectors were thoroughly brushed with repeated gentle movements inside plastic trays filled with filtered seawater. Detached spat were then screened, separated from debris, and preserved in 4% buffered formaldehyde for further counting and measurements. Initial sampling indicated two different densities of spat in different setting tanks, which are hereafter termed “high” (340 scallops/collector, SE = 54.7) and “low” (150 scallops/collector, SE = 47.0) densities. Deployment was undertaken by scuba diving, spat bags being tied at depths of 4 and 12 m from the surface to two ropes hanging perpendicularly from the long-line. A 2-kg weight was attached to the bottom of each drop line. Spat bags (high and low densities) were tied individually to the ropes at 4 and 12 m. In this manner, a factorial design with two replicates was used to evaluate the effects of depth and density on growth of postlarval scallops. Control collectors were deployed in the sea simultaneously to the experimental units to monitor wild scallop settlement. All collectors were retrieved 26 days after deployment (38 days post-set) and transferred to the laboratory.

In experiment 2, carried out from early June to early July 2001 (late autumn–early winter), postlarval scallops were transferred to the field 15 days after settlement. The collectors, spat bags, and procedures were similar to experiment 1. As initial sampling indicated that numbers of spat/collector were similar among setting tanks (401 scallops/collector, SE = 95.9), single spat-bags (1 collector/bag) were tied to triplicate ropes hanging perpendicularly to the long-line at 4 and 12 m depth. Collectors were retrieved 27 days after deployment (42 days post-set) and transferred to the laboratory, where spat were detached and sampled as previously described.

For both experiments, the initial shell height before deployment (maximum dorso-ventral distance perpendicular to the umbo) (n = 30) and final shell height at retrieval (n = 30/spat bag) were determined with an ocular micrometer. To estimate the degree of clogging of the spat bags, individual bags from both experiments were thoroughly scrubbed inside plastic containers after retrieval. The sediments and fouling material deposited in the containers were collected on preweighed 0.5 m \times 0.5 m cellulose filter papers folded into a funnel shape. The filters were then dried for 72 h at 60°C, cooled in a desiccator, and reweighed to determine the dry

Figure 1. Location of the study site off Porto Belo Point (*), (Lat. 27°07'S; Long. 48°30.8'W), Porto Belo, Santa Catarina State (SC), Brazil.

weight of the sediments and fouling material attached to the external spat bags.

Environmental Variables

Water samples from 4- and 12-m depths were taken weekly at the field site using a 2-L Van Dorn sampling bottle. Samples were transferred to the laboratory in a cooler containing ice packs. Temperatures at both depths were recorded hourly with Stowaway data loggers, and dissolved oxygen was determined *in situ* with a digital dissolved oxygen meter (YSI model 55/12FT). In the laboratory,

water samples were gently stirred and filtered through a 350- μ m-mesh screen to remove larger zooplankton. Total suspended particulate matter was determined gravimetrically after filtering 400 mL seawater through a 24-mm-diameter Whatman 934-AH glass microfiber filter (nominal pore size 1.5 μ m) and drying for 72 h at 60°C. Particulate organic (POM) and inorganic matter (PIM) were determined by weight loss on ignition at 450°C (Parsons & Dadswell 1992). Chlorophyll-*a*, an index of phytoplankton biomass, was determined with a Turner digital fluorometer (TD 10-AU) after filtering triplicate, 100-mL water samples (Whatman 934-

AH) and extracting chloropigments in 90% acetone using standard methods (Method. 445.0, USEPA 1997). Salinity was determined by a digital WTW Multiline P4 water quality meter. All variables were determined in triplicate samples.

Statistical Analyses

Data were analyzed with the SPSS statistical package (version 10). Residuals were checked graphically for normality and homoscedasticity (Sokal & Rohlf 1995). A factorial design was used in experiment 1, and a two-way ANOVA ($\alpha = 0.05$) was performed to test for differences in shell heights and percentage retrievals at different depths and densities, using depth and density as fixed factors. In experiment 2, an independent sample *t*-test was used to determine the differences in shell height and percentage retrieval between depths.

RESULTS

Growth

In experiment 1, carried out from mid-March to mid-April 2001, postlarval scallops were deployed in the sea at an initial mean shell height of 0.40 mm. After 26 days of immersion, the mean shell height of scallops at 4 m depth was 5.07 mm (SE = 0.13) and 5.67 mm (SE = 0.16) for collectors with high and low densities, respectively (Fig. 2A), whereas at 12 m the corresponding shell heights were 3.28 mm (SE = 0.10) and 3.60 mm (SE = 0.11). Final shell height was significantly greater at 4 m than at 12 m (ANOVA, $F = 232.4$; $df = 1, 236$; $P < 0.001$) and also greater at low stocking density than at high density (ANOVA, $F = 13.31$; $df = 1, 236$; $P < 0.001$). The interaction between density and depth was not significant ($P = 0.26$). The resulting daily growth rates (DGR) at 4 m were $0.179 \text{ mm day}^{-1}$ and $0.203 \text{ mm day}^{-1}$ for scallops grown at high and low densities, respectively, whereas at

12 m, DGR was $0.110 \text{ mm day}^{-1}$ and $0.123 \text{ mm day}^{-1}$, respectively.

In experiment 2, carried out from early June to early July 2001, postlarval scallops were deployed in the sea at an initial mean shell height of 0.43 mm. No significant difference in mean shell height was detected between depths (*t* test, $t = 1.93$; $df = 1, 178$; $P = 0.056$). Mean shell height at retrieval (after 27 days) was 4.34 mm (SE = 0.25) at 4 m and 4.12 mm (SE = 0.15) at 12 m (Fig. 2B). DGR was 0.144 and $0.137 \text{ mm day}^{-1}$ at 4 and 12 m, respectively.

The dry weight of sediments attached to the spat bags on retrieval was 33.05 g (SE = 1.47) and 30.06 g (SE = 2.16) for 4 m and 12 m, respectively, in experiment 1 and 35.01 g (SE = 1.55) and 34.18 g (SE = 5.12) for 4 m and 12 m, respectively, in experiment 2. There was no significant difference in the sediment content between depths in both experiments, eliminating sediment load as a factor influencing growth rate (*t*-test, $t = 1.5$, $df = 1, 4$; $P = 0.10$ in experiment 1 and $t = 0.99$, $df = 1, 6$; $P = 0.18$ in experiment 2). No wild spat of *N. nodosus* settled on the control collectors in each experiment.

Percentage Retrievals

In experiment 1, the mean number of spat retrieved from the collectors at 4 m was 247 (SE = 42) and 111 (SE = 10) for high and low densities, respectively, whereas at 12 m, the number of spat per collector was 245 (SE = 87) and 122 (SE = 2), respectively. The percentage retrievals were similar between depths and densities (ANOVA, $F = 0.05$; $df = 3, 4$; $P = 0.9$), ranging between 72.2% and 81.3% (Fig. 3A). In experiment 2, the mean number of spat retrieved per collector was 317 (SE = 28) and 278 (SE = 54) at 4 m and 12 m, respectively. Percentage retrievals

were similar between depths (*t*-test, $t = 0.64$; $df = 4$; $P = 0.56$), ranging from 69.3% to 79.05% (Fig. 3B).

Environmental Variables

Temperature

Water temperature in experiment 1 (March–April), recorded hourly, was highly variable (Fig. 4A), especially in the first 2–3 wk of the experiment (March), after which the water column became homogeneous (April). At 12 m, temperature variability (CV = 10.4%) was greater than at 4 m (CV = 5.3%) and temperatures were lower. The mean temperature at 4 m was 25.3°C, with a maximum of 28.2°C and a minimum of 19.6°C. At 12 m, mean temperature was 22.8°C, with a maximum of 27.2°C and a minimum of 17.8°C. On several occasions in March, temperature at 12 m varied by 6–9°C within a 24 h period.

In experiment 2, from early June–early July, temperature was uniform throughout the water column and thus similar at both depths (Fig. 4B). The mean temperature was 20.4°C and 20.1°C at 4 and 12 m, respectively. Whereas maximum temperature at 4 m and 12 m was 22.2°C and 21.7°C, respectively, the minimum temperature at both depths was 17.8°C.

Salinity

There was negligible variation in salinity at 12 m (mean = 33.3%) throughout experiment 1 (Fig. 5A), whereas at 4 m mean salinity was 32.2%, and a lower value (29%) was recorded on one occasion. In experiment 2, the water column was homogeneous with mean salinities of 32.1% and 32.4% at 4 m and 12 m, respectively.

Chlorophyll-*a*

The concentration of chlorophyll-*a* was highly variable during experiment 1, and there were marked differences between 4 and 12 m (Fig. 5B). The mean concentration at 12 m ($1.16 \mu\text{g L}^{-1}$) was

Figure 4. Hourly temperature at 4 m and 12 m depth off Porto Belo Point: (A) experiment 1 (March–April 2001); (B) experiment 2 (June–July 2001).

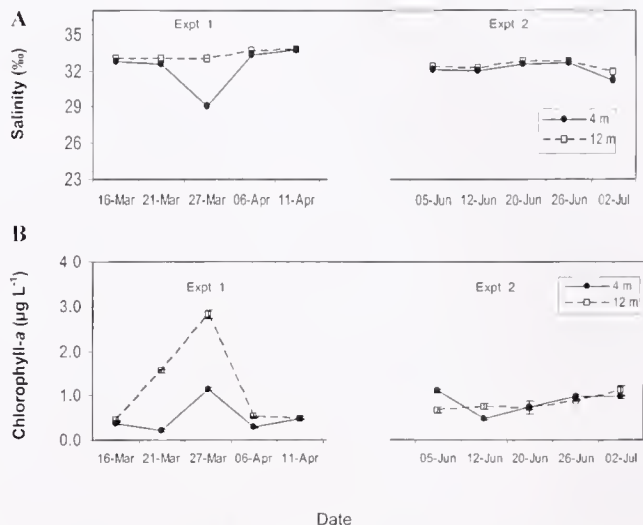

Figure 5. (A) Salinity (‰) and (B) chlorophyll-*a* ($\mu\text{g L}^{-1}$) at 4 m and 12 m depth off Porto Belo Point during experiments 1 (March–April 2001) and 2 (June–July 2001) (mean \pm SE; where bars not visible, SE is too small to plot).

more than twice that at 4 m ($0.5 \mu\text{g L}^{-1}$). Maximum concentrations at 12 m reached 1.55 and $2.82 \mu\text{g L}^{-1}$ in samplings 2 and 3, respectively, which coincided with periods of sharp differences in temperature between 4 and 12 m. At 4 m, mean concentrations were $0.21 \mu\text{g L}^{-1}$ and $1.15 \mu\text{g L}^{-1}$, respectively, for these samplings. In experiment 2, on the other hand, variability in chlorophyll-*a* was relatively small and there were negligible differences between depths. At 4 m the mean value of chlorophyll-*a* was $0.85 \mu\text{g L}^{-1}$, whereas at 12 m it was $0.82 \mu\text{g L}^{-1}$.

Seston

Total particulate matter (TPM) was highly variable in experiment 1 and was higher at 12 m (mean = 2.17 mg L^{-1}) than at 4 m (mean = 1.16 mg L^{-1}) (Fig. 6A), whereas in experiment 2 there were negligible differences in TPM between 4 m (mean = 1.56 mg L^{-1}) and 12 m (mean = 1.71 mg L^{-1}), and TPM was higher toward the end of the experiment.

In experiment 1, particulate inorganic matter (PIM) was higher at 12 m, averaging 1.76 mg L^{-1} , whereas at 4 m, mean PIM was 0.69 mg L^{-1} (Fig. 6B). Particulate organic matter (POM) followed a similar pattern at both depths with a mean of 0.47 mg L^{-1} at 4 m and 0.44 mg L^{-1} at 12 m (Fig. 6C). PIM as percentage of TPM was higher at 12 m (mean = 81.4%) than at 4 m (mean = 59.6%) (Fig. 7A). In contrast, in experiment 2, PIM values were similar at 4 and 12 m, averaging 1.10 mg L^{-1} and 1.14 mg L^{-1} , respectively (Fig. 6B). Differences in POM levels between 4 m (mean = 0.46 mg L^{-1}) and 12 m (mean = 0.57 mg L^{-1}) were negligible (Fig. 6C). As a result, mean PIM as a percentage of TPM was 69.7% and 65.2% at 4 and 12 m, respectively (Fig. 7A).

Dissolved Oxygen

In experiment 1, dissolved oxygen was higher at 4 m, where percent saturation ranged from 82.8% to 92.1% (mean = 91.1%) (Fig. 7B), than at 12 m (mean = 75.3%), where minimum levels reached 61.9% and 48.8%. These dissolved oxygen minima coincided with periods when the temperature at 12 m was about 6°C lower than at 4 m. In experiment 2, mean percent oxygen saturation was 90.82% and 84.50% at 4 m and 12 m, respectively.

DISCUSSION

Growth

Differences in growth of postlarval *Nodipecten nodosus* were recorded between 4 and 12 m in experiment 1 during late summer–early autumn. Scallops attained a larger size near the surface, where the growth rate was approximately 1.6 times higher than at 12 m. However, in experiment 2 (late autumn–early winter), growth of scallops was similar at both depths. Whereas similar growth rates in experiment 2 may be explained by the homoge-

neous conditions throughout the water column, the differential growth recorded in experiment 1 may be attributed to differences in environmental factors between depths.

This is the first study to report the influence of a subsurface intrusion of cold water with higher phytoplankton biomass in a coastal aquaculture area in southern Brazil and to demonstrate its significant effect on bivalve farming. Although food quantity, as expressed by concentration of chlorophyll-*a*, was higher at 12 m in experiment 1, growth of postlarval scallops was lower. Differences in mean temperature between depths were probably too small (2.5°C) to account for the observed differences in growth. However, the higher temperature variation on a short time-scale recorded at 12 m, together with the longer exposure period to lower temperatures, may have stressed the scallops, thus limiting growth. In addition, whereas the temperature dropped below 20°C at 4 m for only 4 h, at 12 m this persisted for at least 78 h, a period in which growth rates could have been reduced. Growth in bivalves is an integrated response to food availability and temperature (Bayne & Newell 1983, MacDonald & Thompson 1985, Bricelj & Shumway 1991, Parsons & Dadswell 1992, Côté et al. 1993). No studies on bivalve growth have considered the effects of temperature variation on such a short time-scale as in the current study (ca. semi-daily). In a study by Pilditch & Grant (1999), temperature variation on an 8-day cycle had a negligible effect on growth and metabolism of juvenile scallops *Placopecten magellanicus* under laboratory conditions. Scallops did not acclimate to the temperature cycles, displaying metabolic rates tightly coupled with water temperature, which is also in agreement with Shumway et al. (1988), who found that metabolic rates of *P. magellanicus* follow the seasonal and laboratory acclimation temperatures. In Newfoundland, feeding and metabolic rates of *P. magellanicus* are also correlated with environmental temperature, as well as food availability (MacDonald & Thompson 1986). In contrast, Widdows (1976) demonstrated compensatory acclimation to temperature in the mussel (*Mytilus edulis*). A strong dependence of physiologic rates on environmental temperature in scallops suggests that the periods of lower temperature may have depressed physiologic rates in *N. nodosus*, contributing to the observed reduction in growth during periods of lower temperature.

PIM as a percentage of TPM is an important environmental factor affecting growth of bivalves. The amount of PIM in seawater dilutes POM, reducing the nutritional value of seston for scallops (Vahl 1980, Wallace & Reinsnes 1985, Bricelj & Shumway 1991, Emerson et al. 1994). For example, when PIM reaches a critical value of about 80% of TPM, *Chlamys islandica* cannot absorb POM, resulting in a reduction of feeding rate, thus reducing or stopping growth (Vahl 1980). Although certain bivalves (including some scallops) can selectively ingest organic particles to compensate for dilution of food quality (Widdows et al. 1979, Bricelj & Malouf 1984, MacDonald & Ward 1994), *P. magellanicus* lacks this ability at high PIM concentrations (Bacon et al. 1998). In experiment 1, percent PIM was markedly higher at 12 m than at 4 m, averaging 81.4% and reaching a maximum of 90.5%. Thus, the benefits of higher food abundance, as expressed by levels of chlorophyll-*a*, were probably offset by the negative effect of a higher inorganic content of seston, resulting in significantly lower growth rates at 12 m. It is therefore difficult to decouple the effects of temperature and inorganic content of the seston when determining which was the major factor affecting growth, as high PIM was associated with temperature oscillations in experiment 1. It is more likely, however, that an interaction of both variables

Figure 7. (A) Percentage of inorganic matter in relation to total seston (% PIM) and (B) percent oxygen saturation at 4 m and 12 m depth off Porto Belo Point during experiments 1 (March–April 2001) and 2 (June–July 2001).

contributed to the slower growth recorded at 12 m. In general, POM concentrations were similar between depths, but on one occasion an unusual situation arose in which POM was higher at 4 m, but chlorophyll-*a* was higher at 12 m. This coincided with a low salinity event at 4 m, probably caused by continental runoff due to rainfall, which may have exported terrigenous organic matter.

The food supply for cultured bivalves is also largely influenced by water flow and the concentration, size, and quality of food particles (Grant 1996). It is unlikely that water flow differed between 4 and 12 m in the current study, causing differences in growth, because such differences would have also been observed in experiment 2, in which growth was similar between depths. The size and quality of the suspended particles removed by bivalves is dependent on the phytoplankton species composition, which was not evaluated in the current study. The possibility that phytoplankton composition differed between depths in experiment 1 cannot therefore be ruled out and requires further investigation. Although several studies have examined the phytoplankton composition in coastal and oceanic regions of southern Brazil (citations in Soares 1983), none have focused on the phytoplankton composition of subsurface intrusions of SACW. Nevertheless, from an aquaculture perspective, it is significant that during summer-early autumn, the coastal culture site is under the influence of a thermocline oscillation caused by the proximity of SACW, and under these circumstances, nutritional and thermal conditions are less favorable for growth of postlarval scallops.

Brandini et al. (2000) proposed that if bivalves were grown offshore in southern Brazil in depths influenced by SACW, growth would be maximized due to higher food abundance as expressed by levels of chlorophyll-*a*. The current study suggests that growing scallops below the thermocline during the SACW intrusion may not necessarily be beneficial, as other concurrent factors may neutralize the benefits of enhanced food levels. It is possible, however, that the influence of SACW on growth may vary according to the species under consideration. *Nodipecten nodosus* occurs in tropical waters (Smith 1991), and the study area is at its southern limit of distribution in the Southern Hemisphere, where minimum temperatures reach levels reducing growth rates (Rupp 2003). Furthermore, scallops display low tolerance for high PIM (examples in Bricelj & Shumway 1991). Therefore, it is suggested that if *N. nodosus* is cultured in open areas of southern Brazil, growth will be enhanced if the culture nets are suspended in waters above the influence of SACW. Conversely, other species, such as the Pacific oyster *Crassostrea gigas* and the mussel *Perna perna*, which are currently cultured in embayments in southern Brazil, may grow well if cultured under SACW influence. Unlike scallops, intertidal bivalves are usually more tolerant of temperature variability and high PIM levels (Bayne 1976, Newell & Langdon 1996, Shumway 1996). The influence of environmental instability on bivalve growth associated with SACW intrusions requires further examination before aquaculture expands further to deeper waters off southern Brazil.

In the current study, postlarval scallops cultured at a higher stocking density (340/bag) displayed a slight but statistically significant reduction in growth compared with those grown at lower density (150/bag) at both depths in experiment 1. Grecian et al. (2000), however, found no difference in growth of *Placopecten magellanicus* at stocking densities of 2600 and 5200 spat/bag, but the surface area of the spat bags and the mesh opening were larger than those used in the current study, so a direct comparison is difficult. A negative relationship between growth and stocking

density inside culture nets has been described for other scallops (Duggan, 1973, Ventilla 1982, Parsons & Dadswell 1992, Côté et al. 1993, Côté et al. 1994, Maeda-Martinez et al. 1997, Román et al. 1999). Parsons & Dadswell (1992) postulated that at higher stocking densities, intraspecific competition for food reduces its availability per individual, limiting growth. Higher densities also lead to frequent contact among organisms, which may induce irritation, retraction of the mantle, or valve closure, resulting in reduced feeding rates, and may also cause breakage of shell margins (Côté et al. 1993). Within the range of densities tested, the reduction in growth at higher density was slight, so it would be more cost-effective to grow postlarval *N. nodosus* at the higher density. This strategy, however, is only appropriate if the spat bags are retrieved after an immersion period of about 26–30 days, as in the current study, when scallops at 4 m in experiment 1 reached a mean size (>5 mm) at which they could be transferred to pearl nets. On the other hand, if the spat bags are to be immersed for longer periods before spat are detached and transferred to pearl nets, it is likely that the density influence on growth will increase as scallops attain larger sizes.

A comparison of daily growth rates can be made between the high density treatment in experiment 1 (350 scallops/bag; SE = 54.7) and experiment 2 at both depths (401 scallops/bag; SE = 95.9), in which stocking densities were equivalent. Though the lowest DGR was recorded in experiment 1 at 12 m (0.110 mm day⁻¹), and the highest at 4 m (0.179 mm day⁻¹), DGR in experiment 2 was not significantly different between depths (0.144 and 0.137 mm day⁻¹ at 4 and 12 m, respectively). Lower growth rates at 12 m in experiment 1 can be explained by differences in environmental factors between depths, as previously noted. Differences in DGR between 4 m in experiment 1 and both depths in experiment 2 can be explained by seasonal differences in temperature, because chlorophyll-*a*, seston, salinity, and oxygen were similar at 4 m in experiment 1 and at both depths in experiment 2 and therefore cannot account for observed differences in growth. Temperature, on the other hand, was significantly lower in experiment 2 (mean = 20.4°C and 20.1°C at 4 and 12 m, respectively) than in experiment 1 at 4 m (mean = 25.6°C). This difference probably accounted for differences in growth between seasons, in accordance with the results of Rupp (2003), which showed that seasonal variation in temperature, rather than food availability, explained differences in DGR of postlarval *N. nodosus*.

Percentage Retrievals

Percentage retrievals of postlarval *N. nodosus* were similar between depths and experiments and ranged from 69.3% to 81.3%. These values are higher than those reported in Heasman et al. (2002) (25.4%) for *Pecten fumatus*, in which postlarval scallops at a shell height of 0.5 mm were deployed in the sea-based nursery attached to monofilament collectors, as in the current study. Stocking density, as well as the variability in environmental factors recorded in the current study, had a negligible effect on retrieval of scallops, even when they experienced sudden temperature changes at 12 m in experiment 1. Dickie & Medcof (1963) reported mass mortalities of adult scallops *Placopecten magellanicus* in Atlantic Canada due to a sudden change in the position of the thermocline. In southern Brazil, *N. nodosus* cultured at 12 m can experience sudden temperature shocks on a semi-diurnal basis in magnitudes similar to the seasonal temperature variation, but such variation did not cause spat mortality. Temperatures in the current study did not reach the lethal levels determined by Rupp & Parsons (in press).

Environmental Variables

During the first 2–3 wk of experiment 1 (March), scallops at 12 m were influenced by an oscillating water mass with thermal characteristics different from the upper layer, with the result that temperature variability at 12 m was greater than at 4 m. A colder bottom water mass frequently influenced the 12 m layer but only occasionally reached 4 m. These differences in water masses between depths resulted in a temperature range of 10.4°C between 4 m and 12 m in less than 24 h, resulting in a semi-diurnal variability in temperature equivalent to that observed on a seasonal time scale (Rupp 2003). Such cold water intrusions disappeared toward the end of experiment 1 (April) and were not observed in experiment 2 (June–July). Furthermore, maximum values of chlorophyll-*a* were recorded in March, when concentrations at 12 m were higher than at 4 m. Such spatial variation in temperature and chlorophyll-*a* is in agreement with the patterns reported in other studies for the inner continental shelf of southern Brazil when SACW is present (Brandini 1990, Borzone et al. 1999). There is strong evidence that scallops held at 12 m in experiment 1 were under the influence of an oscillating water mass that can be identified as predominantly SACW. SACW has been characterized as a cold water mass (10–20°C) affecting lower layers of the continental shelf (Matsuura 1986, Castro & Miranda 1998) with relatively higher concentrations of nutrients and chlorophyll-*a*, lying underneath warmer Coastal Waters (CW), which are relatively oligotrophic (chlorophyll-*a* < 0.4 µg L⁻¹) off Santa Catarina State during summer (Brandini 1990). Borzone et al. (1999) indicated that from December to April (summer–early autumn), the water column on the inner continental shelf displayed a marked thermocline, with near-surface temperatures reaching 27°C, whereas below the thermocline, the temperature was 16°C and a chlorophyll-*a* maximum of ca. 3 µg L⁻¹ was recorded. This gradient was attributed to SACW intrusions. Conversely, from May to September (late autumn–winter–early spring), the temperature gradient disappeared with vertical mixing of the water column (Borzone et al. 1999). During this period, SACW retreats toward the shelf break (Castro & Miranda 1998), and the inner continental shelf becomes influenced by cold (<20°C), low salinity water (29–35‰) of sub-Antarctic origin (SAW), leading to a vertically mixed water column (Sunyé & Servain 1998). These observations are consistent with the recorded differences in temperature between experiments 1 and 2 in the current study. The salinity reported for SACW is around 35‰ (Matsuura 1986, Castro & Miranda 1998), and salinity at 12 m remained close to 33‰ throughout the current study. According to Castro & Miranda (1998), mixing of SACW and CW occurs across the continental shelf during summer. The water resulting from this interaction, retaining the major characteristics of SACW (relatively low temperature and high chlorophyll-*a* but with slightly lower salinity), is probably the water mass that repeatedly affected the culture site at 12 m during summer, causing strong thermal instability. Moreover, during summer, when the upper layers of the inner continental shelf are dominated by warm CW, the only reports of waters colder than 20°C in the South Brazil Bight are for areas affected by SACW (Castro & Miranda, 1998), providing further evidence that the cold waters affecting lower layers of the coastal aquaculture site originated from SACW.

The oscillation of the cold water mass at the study site during summer may have been a result of tidal influence or wind stress. Penetration of SACW onto the continental shelf has been related to situations in which prevailing winds blow offshore, generating a

cross-shelf circulation toward shore in the deeper layers (Castro & Miranda, 1998). However, the short-term variability in the position of SACW has not been investigated in detail. The factors influencing hydrographic processes in shallow coastal areas are complex and vary greatly on short spatial and temporal scales (Mann & Lazier, 1991). The study region is characterized by a microtidal regimen, which may have contributed to the oscillation of the cold water mass, but the small tidal amplitude may not have been sufficient to destabilize the thermocline and generate vertical mixing throughout the water column. The spatial and temporal dynamics of SACW along the southeastern coast of Brazil are still poorly understood, and the implications of SACW intrusions on aquaculture require further study.

Another important environmental factor that markedly differed between 4 and 12 m in experiment 1, but not in experiment 2, was PIM, which was higher at 12 m. No previous study carried out in southern Brazil has investigated the organic and inorganic contents of the seston associated with different water masses. The higher percent PIM near the bottom recorded in experiment 1, but not in experiment 2, is possibly associated with SACW, suggesting that during the process of SACW intrusion into the lower layer across the continental shelf, a frictional shear on the substrate resuspends bottom sediments, resulting in the higher PIM in the SACW. According to Borzone et al. (1999), the bottom sediments of the inner continental shelf of the SBB are formed by quartz sand with a silt-clay fraction that increases with depth. These fine sediments could be resuspended in the water column, increasing PIM levels of SACW. A further indication of the deeper origin of the water mass affecting the bottom layers is dissolved oxygen, which was lower at 12 m on two occasions, once falling below 50%. According to Longhurst & Pauly (1987), waters originating from deeper layers of the ocean often contain less oxygen than surface waters.

In conclusion, the influence of environmental factors associated with depth at an aquaculture site in southern Brazil varied seasonally, depending on the subsurface intrusion of SACW. The characteristics of this water mass were less favorable for postlarval scallop growth than those of near-surface waters. During summer–early autumn, lower temperature and sudden temperature changes, together with a higher inorganic content of the seston associated with SACW, resulted in slower growth of postlarval *N. nodosus* at 12 m than at 4 m. Furthermore, on several occasions, the vertical thermal gradient from 4 to 12 m (10°C) was similar to the seasonal temperature variation. Conversely, during late autumn–early winter, the water column was vertically mixed, and scallop growth was similar at both depths. Higher temperatures explained higher growth rates near the surface during summer–early autumn compared with lower growth in late autumn–early winter at both depths. Furthermore, growth of postlarval scallops cultured in spat bags showed an inverse relationship with stocking density, but the differences were small and it would be more cost-effective to grow postlarval scallops at the higher density tested. It is suggested that during summer–early autumn, if the site is subject to SACW intrusions, suspended nursery culture of scallops should be undertaken above the thermocline to maximize growth.

ACKNOWLEDGMENTS

This research was supported by a CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico, Brazil) Ph.D. scholarship to G.S.R. and by the Brazilian Mariculture Linkage Program (BMLP), Canada. The Laboratory for the Culture of Marine Mol-

luses (LCMM). Federal University of Santa Catarina, provided experimental facilities and technical assistance. We particularly thank Cheryl Brooking and Marcos Albuquerque for help with the

experiments and Drs. Pat Dabinett, Sandra E. Shumway, David Innes, and Don Deibel for valuable comments on an earlier version of the manuscript.

ABSTRACT Triploid organisms have a limited capacity to develop gonads, and thus are considered sterile or partially sterile. The objective of this study is to compare triploid and diploid organisms of the same age, and grown under similar conditions during a 1-year period, to determine to what extent sterility affects size and number of adductor muscle cells, and accumulation of biochemical reserves at first maturation. Adult catarina scallops (*Argopecten ventricosus*) were matured, and eggs were treated with cytochalasin-B to induce triploidy. Untreated diploid controls and triploids were grown in Bahía Magdalena, Mexico in Nestier trays at 3 m depth from April 2000 to March 2001. Scallops were sampled monthly from June 2000. The gonadosomatic index (GSI) was significantly larger in diploid organisms, whereas the muscle index was larger in triploid organisms. A small proportion (40%) of diploid scallops exhibited reproductive activity during the first year. In spite of high GSI, the gonads of triploid scallops were mostly immature, except for some individuals that formed mature oocytes by March 2001. Triploids had 123% higher adductor muscle weight than diploid scallops at the end of the sampling period, and most of this increased gain was a result of adductor muscle cell size (hypertrophy), and not cell number (hyperplasia). Total lipids and proteins concentrations were significantly larger in the gonads of diploid scallops. Muscle carbohydrates were significantly larger in triploid scallops, which suggests decreased transference of carbohydrates from muscle to gonad in triploid sterile organisms.

KEY WORDS: energy-of-allocation, gonad, maturation, muscle, oocytes, Pectinidae, reproduction, *Argopecten*

INTRODUCTION

During the reproductive period of pectinids, there is an important accumulation of lipids and proteins in the gonads (Barber & Blake 1981, Barber & Blake 1985, Martínez 1991, Pazos et al. 1996), mostly provided by food or mobilization of endogenous reserves when food is not readily available (Barber et al. 1991). The adductor muscle of pectinids is the site of one of the largest reserves of glycogen and protein mobilized during maturation (Barber & Blake 1981, Barber & Blake 1985, Epp et al. 1988). When reproductive activity begins, there is a large transfer of biochemical components to the gonad, and the weight of the muscle decreases. Also, water content in the adductor muscle is modified, and this can affect its taste and texture and thus its market price (Allen & Downing 1991). Triploid organisms have limited capacity to mature, and in most species where triploidy is attained, individuals do not produce gametes or viable larvae, and are considered sterile. An advantage of sterile organisms is that they transfer less biochemical energy to the gonad, so other tissues can gain more weight over time. For this reason, triploidy has been induced in pectinids (Tabarini 1984, Beaumont 1986, Komaru & Wada 1989, Ruiz-Verdugo et al. 2000, Yang et al. 2000, Maldonado-Amparo et al. 2004) and other mollusks of commercial interest (for review, see Beaumont & Fairbrothers 1991). The adductor muscle weight of triploid catarina scallops can be 182% that of diploids after 280 days of grow-out (Ruiz-Verdugo et al. 2000). In catarina scallop, reproduction has a significant impact on meat (muscle), because commercial scallops are harvested at 1 year (6-cm length), and first maturation age can be as early as 4 months or 2-cm length (Cruz et al. 2000). Although triploid muscle weight gain is assumed to result from less transfer of biochemical energy from the muscle to the gonads (Ruiz-Verdugo et al. 2001b), no studies have analyzed the effect of increased muscle energy re-

serves on muscle fiber growth (hypertrophy) or number (hyperplasia). An increase in muscle fiber numbers or size can have different effects on the texture of the muscle. The objective of this study is to compare triploid and diploid organisms of the same age and grown under the same conditions during a 1-year period, to determine to what extent sterility affects the biochemical reserves accumulated in muscle, and the size of adductor muscle cells.

MATERIAL AND METHODS

Adult catarina scallops (*Argopecten ventricosus*) were matured under laboratory conditions at CIBNOR, as described by Ramírez et al. (1999). For triploid induction, eggs were treated with 0.5 mg/L cytochalasin-B (CB) during 15 min. after 50% of eggs were in the first polar division, as described by Ruiz-Verdugo et al. (2000). Untreated diploid controls and treated organisms (containing triploids and diploids) were transported to Laguna Rancho Bueno (Bahía Magdalena, B.C.S., Mexico) where they were grown separately in Nestier trays at 3 m depth (Ruiz-Verdugo et al. 2000).

A total of 30 scallops (from both CB-untreated and treated groups) were collected at approximately monthly intervals from the grow-out area at Laguna Rancho Bueno from June 2000 to March 2001 and transferred to the laboratory at CIBNOR. Upon arrival, total live animal weights, and shell-free tissue weights (biomass) of all samples were recorded. Adductor muscle and gonad weight were recorded from July 2000 to the end of the study in March 2001. Organ indices for the two tissues were calculated as the proportion of organ wet weight to total tissue weight minus gonad weight, to eliminate any effect of on-going maturation.

$$\text{GSI (\%)} = (\text{gonad wet weight (g)} \times 100) / (\text{total wet biomass (g)} - \text{gonad wet weight (g)})$$

$$\text{MSI (\%)} = (\text{muscle wet weight (g)} \times 100) / (\text{total wet biomass [g]} - \text{gonad wet weight [g]})$$

Triploidy condition was verified individually in samples of mantle tissue using flow cytometry (Maldonado-Amparo et al. 2004). Un-

*Corresponding E-mail: epalacio@cibnor.mx

treated control organisms and CB-treated diploid scallops were grouped together for statistical analyses. True triploids ranged from 60% to 93.3% in the CB-treated group along each sampling period (Fig. 1), which is similar to the induced triploids of catarina scallop reported by Ruiz-Verdugo et al. (2001a).

Gonad development was evaluated macroscopically during sampling based on stages described by Sastry (1968)—immaturity, partial maturity, maturity, and spent—but including also a “non-active” stage. In addition, a portion of the gonad was fixed in formaldehyde, embedded in paraffin-paraplast mixture, sectioned (6–8 μm), and stained with Harris hematoxylin-eosin (Humanson 1972). Maturation stages of 10 to 15 scallops per sampling were assessed using the classification for triploid and diploid organisms of this species proposed by Ruiz-Verdugo et al. (2000a), and Maldonado-Amparo and Ibarra (2002a).

A portion of the adductor muscle was fixed in 10% formaldehyde, embedded in paraffin-paraplast mixture, sectioned transversely (4–6 μm), and stained with Harris hematoxylin-eosin (Humanson 1972). The number of fibers in a fixed area of striated muscle in diploid and triploid scallops was counted. The diameter of individual striated muscle fibers ($n = 30$ fibers) was assessed using an image analyzer (Image-Pro), and photographed using a microscope ($\times 40$). It was observed that the surrounding connective tissue allowed for an increase in muscle fiber size and it was assumed that this increase was not affecting the number of cells/area.

Gonad and muscle samples were homogenized with a mechanical homogenizer in 1.5 mL of cold, saline solution (NaCl, 35 g/L) to obtain a crude extract, from which analyses for total protein, carbohydrates, and lipids, were done as described in previous works (Ruiz-Verdugo et al. 2001b, Racotta et al. 2003). Lipids were analyzed by the sulpho-phosphovanillin method after mixing 100 μL of the crude extract with 1-mL sulfuric acid and heating

the mixture to 90 °C (Barnes & Blackstock 1973). The amounts of gonad in July and August 2000 samples were not sufficient for analysis. Carbohydrates were analyzed after precipitating proteins from the crude extract with 20% trichloroacetic acid (1:2) and centrifuging at $3000 \times g$, 5 °C for 10 min and mixing the supernatant with four parts of anthrone solution (0.1% dissolved in 76% sulfuric acid), incubated 3 min at 90 °C and cooled to 4 °C to stop further reaction (Van Handel 1965). Soluble proteins were determined in diluted crude extract (1:5 with 0.1N NaOH) (Bradford 1976). The energy conversion factors used were 17.2 kJ/g for carbohydrates, 17.9 kJ/g for proteins, and 33.0 kJ/g for lipids, as described in Heras et al. (1998).

Data are reported as mean \pm standard error (S). Two-way analyses of variance (ANOVA) followed by a Tukey test for unequal n post-hoc mean comparisons (Statistica Version 5.0) were used to assess significant differences among months of sampling and ploidy groups. The level of significance was set at $P < 0.05$. Organ indices were arcsine transformed for the analyses (Sokal & Rohlf 1981), but untransformed data are presented. When there was a significant interaction, a Tukey post hoc to evaluate for differences between diploid and triploid means was performed.

RESULTS

Scallop growth in terms of live weight and tissue biomass are shown in Figure 1. Total or live weight increased continuously from 0.6 g in June 2000, to 33.3 g for diploids and 62.5 g for triploids in March 2001, but significant differences were seen from November 2000 on. Biomass represented 36% of total weight in diploids and 45% in triploids by the end of the sampling period. In March 2001, the biomass of triploids was 88% higher than that of diploids, but biomass differences between diploids and triploids were significant by November 2000.

Gonad weights began to increase earlier in diploid than in triploid scallops, but triploid gonads reached larger weights by March 2001, 2.1 g or 61% higher than the 1.3 g of diploids at that same time (Table 1). Triploid scallops had generally lower gonadosomatic indices (GSI), and higher gonad water content than diploids ($P < 0.01$). Gonad carbohydrates decreased in the triploid group throughout the sampling period, and although the two were not significantly different, the interaction was. In general, there was a greater variation in gonad carbohydrate for triploids than for diploids, with the highest and lowest values both for triploid scallops in October 2000 and February 2001, respectively, which were significantly different to those in the diploid group. Protein and lipid concentrations in the gonads of diploid and triploid scallops were similar from September 2000 to January 2001, but by February 2001 proteins and lipids in diploid gonads increased significantly, decreasing again in March. In the gonads of triploid scallops no increase in protein and lipid was seen in the same period. Energy reserves were similar in gonads of diploid and triploid scallops from September 2000 to January 2001, but increased significantly in gonads of diploid scallops by February 2001, when energy reserves were the lowest ones for triploid scallops, and remained still higher than in triploids in March 2001.

Adductor muscle weight of triploids was 123% greater than that of diploids by the end of the sampling period (Table 2). The muscle index was larger in triploid organisms, except at the beginning of the sampling period, when it was similar to that of diploid scallops. Water content in diploid and triploid muscle was not significantly different, but showed differences related to sampling time, with the lowest values in January 2001 for both groups.

Figure 1. Growth (mean \pm S) of diploid and triploid catarina scallops (*Argopecten ventricosus*). Open circles = diploid total live weight; solid circles = triploid total live weight; open squares = diploid tissue biomass; solid squares = triploid tissue biomass. Data were analyzed with a two-way ANOVA, with ploidy groups as the first main factor ($P = 2$ levels, diploid and triploid scallops), and date of sampling as the second main factor ($S = 9$ levels). The number of diploid (D) and triploid (T) organisms sampled each month is shown at the bottom of the figure. The diploid group includes untreated and CB-treated scallops (see Methods). Significant differences ($P < 0.05$) between diploid and triploid means, as determined by a Tukey post hoc test, are shown with an asterisk.

Data were analyzed by a 2-way ANOVA, with ploidy as the first main factor (P, two levels), and sampling date as the second main factor (S, eight levels except July and August, when sample was insufficient for biochemical analyses).

N.S., Not significantly different. When there was a significant interactions, a Tukey for unequal N post hoc test was applied to compare means between groups, and means with different letters are significantly different ($P < 0.05$).

Muscle carbohydrates and lipids varied seasonally in both ploidy groups, but were generally higher in triploid scallops. In contrast, no differences between diploid and triploid scallops in muscle protein and energy reserves were observed, although seasonal variations were observed in both, with the highest values in October 2000.

Gonad development of diploid scallops varied seasonally, with reproductive activity in July to August and in October 2000, although the distribution of gonads into different macroscopic stages showed mature and spent gonads throughout the sampling period (Fig. 2A). In contrast, triploid scallops were mostly inactive or immature, with partially mature gonads in October 2000, and January and March 2001, and mature gonads only in March 2001. However, no spent gonads were found in triploids during the sampling period. Gametogenesis evaluated in diploid and triploid gonads of catarina scallops during 382 days did not reveal maturation in gonads of triploid scallops (Ruiz-Verdugo et al. 2000). The distribution of the macroscopic stages was in accordance with the

maturation stages evaluated by histology (Maldonado-Amparo & Ibarra 2002a).

The adductor muscle cells of triploids were significantly larger than those of diploids on all sampling dates (Fig. 3A). In January 2001, triploid muscle cells were 53% larger than muscle cells of diploid scallops. The largest difference in cell size was observed in February 2001, when the triploid muscle cell size was three times larger than that in diploids. In March 2001, the cells of triploid scallops increased 31% compared with February, and were 79% larger than those of diploid scallops. In contrast, the number of muscle fibers per area (fiber density) was not significantly different between ploidy groups or as a result of sampling time (see Fig. 3B).

DISCUSSION

One advantage of producing triploid mollusks is that individuals grow more (Allen & Downing 1986, Child & Watkins 1994,

Data were analyzed by a 2-way ANOVA, with ploidy as the first main factor (P, two levels) and sampling date as the second main factor (S, eight levels).

N.S., Not significantly different. When there was a significant interactions, a Tukey for unequal N post hoc test was applied to compare means between groups, and means with different letters are significantly different.

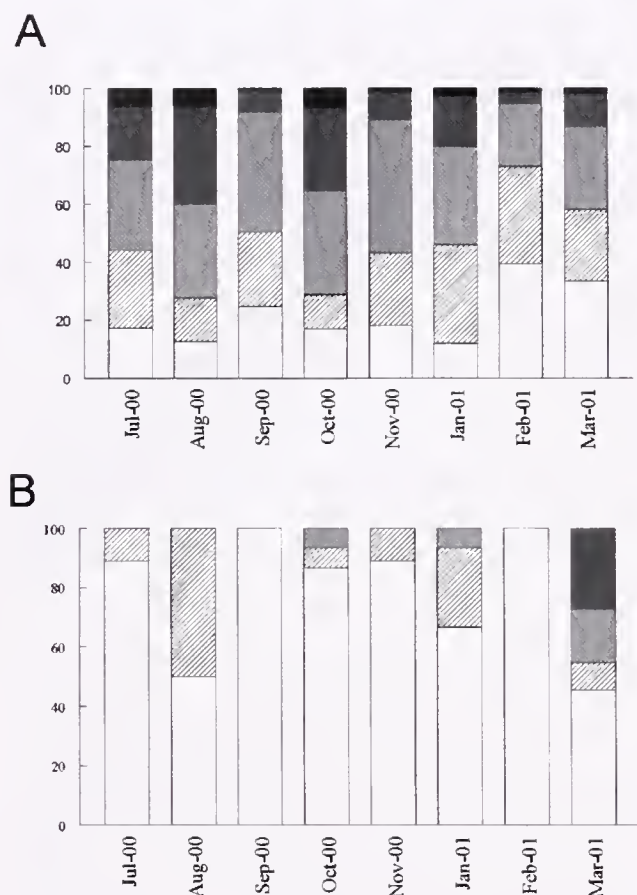

Figure 2. Frequency of diploid (A) and triploid (B) scallops classified into five macroscopic gonadic stages during the sampling period. I = Inactive (open); II = Immature gonad (single line); III = Partial maturation (double line); IV = Mature gonad (crossed lines or hatched); V = spent gonad (black).

Hawkins et al. 1994, Hand et al. 1998, 1999, Kesarcodi-Watson et al. 2001). Several hypotheses have been proposed to explain the higher growth rate of triploids over diploids (Garnier-Géré et al. 2002). A genetic hypothesis is based on the expected higher heterozygosity of triploids (Guo & Allen 1994, Hawkins et al. 2000). Triploids may perform better because of the potential for faster transcription due to the three copies of the same gene (Magoulas et al. 2000). A physiologic hypothesis is based on the sterility of triploids, which would divert more metabolic flux to growth (Allen & Downing 1986, Hand et al. 1999). Guo and Allen (1994) proposed a third hypothesis (i.e., that greater growth in triploid mollusks results from larger size polyploid cells) based on the assumption that a larger nucleus requires a larger cytoplasm so that nutrients and organelles are adequately proportioned during cell division and growth.

Guo and Allen (1994) hypothesized that this resulted in individuals with polyploid gigantism, caused by increased cell volume and a lack of cell number compensation. They stated that the polyploidy gigantism hypothesis needs to be tested directly by studies on cell size, cell number, and organ size in diploids and triploids. Differences in cell size between triploid and diploid mollusks have been reported for eggs (Guo & Allen 1994, Eversole et al. 1996, Ruiz-Verdugo et al. 2001a), sperm (Maldonado-Amparo & Ibarra, 2002b), adductor muscle diameter (Gardner et al. 1996),

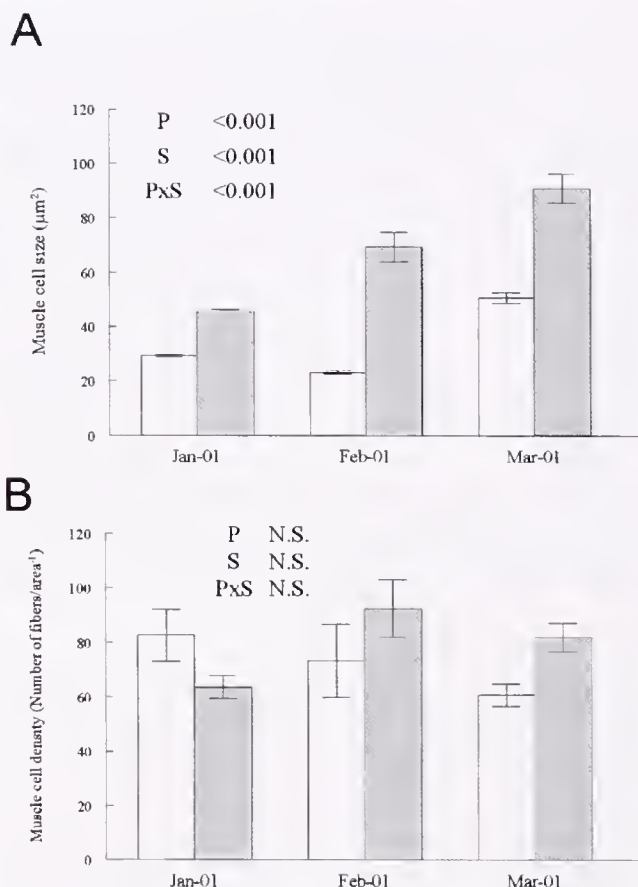

Figure 3. Cell size (A) and cell density (B) of adductor muscle fibers in diploid (white bars) and triploid (single line bars) scallops, analyzed with a two-way ANOVA, considering Ploidy (P = 2 levels: diploid and triploid scallops), and Sampling period (S = 3 levels: January, February, and March of 2001). Anova results are shown in the graph. Means sharing the same letter are not significantly different ($P > 0.05$).

gill tissue cells and hemolymph cell nuclei (Child & Watkins 1994). However, polyploid gigantism might be more apparent in some tissues than in others. For example, in bivalves, the adductor muscle seems particularly susceptible to polyploid gigantism (Guo & Allen 1994). In the present study, we observed that triploid catarina scallops had significantly larger muscle cells diameter (hypertrophy) than their diploid counterparts grown in similar conditions. However, the number of fibers (hyperplasia) in the adductor muscle of triploids was not significantly different from that of diploids, at least during the period tested. Thus, if the number of muscle cells did not decrease to compensate for hypertrophy, a lack of regulation in number of muscle cells is consistent with the polyploid gigantism hypothesis proposed by Guo and Allen (1994).

However, it is difficult to separate hypertrophy caused by polyploidism, and that caused by an increase in energy accumulated in storage tissues per se. This is because, although in most tissues bigger cells might compensate for fewer cells, storage tissues can follow a different pattern. As an example, the adipose tissue in mammals presents hypertrophy as a result of acylglycerides storage (Palacios et al. 1996). This usually happens in adult animals, and it is not accompanied by a decrease in cell number, although there can be an increase in the number of fat cells (hyperplasia). In this work, muscle carbohydrates in triploids increased 5-fold from

January to February, and 2-fold from February to March 2001 (Table 2), corresponding to similar increases in muscle cell size during the same times (see Fig. 3A). In pectinids, where muscle cells are implicated in the storage and mobilization of nutrients to meet reproductive requirements (Mathieu & Lubet 1993), the observed glycogen storage in triploid adductor muscle could be a normal mechanism to accumulate excess energy during periods of high productivity. Thus, we should expect muscle hypertrophy when the conditions are adequate even in diploids, as was the case for diploids sampled at the end of the experiment and compared with those sampled in January 2001 (see Fig. 3A). Therefore, an increase in cell size can be compatible with either larger polyploid cell volume or changes in allocation of energy reserves from muscle to gonad.

The energy allocation hypothesis is based on the sterility or partial sterility of triploid mollusks, and is characterized by triploids growing larger because of energy diverted from reproduction to growth (Stanley et al. 1984, Allen & Downing 1986, Akashige 1990, Barber & Mann 1991, Shpigal et al. 1992, Hawkins et al. 1994, Hand et al. 1998). Differences in growth are not usually detected until the organisms reach first sexual maturity, or until after first spawn (Stanley et al. 1984, Tabarini 1984, Barber & Mann, 1991, Beaumont & Fairbrothers 1991, Hand et al. 1998, Ruiz-Verdugo et al. 2001b). The losses attributable to spawning in a 40-mm shell length hard clam had been calculated by Ansell and Lander (1967) at 20% to 25% of the total energy used for growth. Eversole et al. (1996) concluded that this amount of energy diverted into growth rather than reproduction may account for the difference in size between diploids and triploids. In accordance, we observed higher energy values in the gonads of diploid scallops by the end of the sampling period (see Table 1) than can be interpreted as energy loss for growth. Guo and Allen (1994) concluded that unless diploids spawned thus decreasing their total weight, and triploids did not, the energy reallocation hypothesis could not explain the larger total weight in triploids before sexual maturation. However, in pectinids the adductor muscle is the most important storage tissue with the digestive gland secondary, shown by the decrease in weights during the reproductive period (Barber & Blake 1981, 1985, Epp et al. 1988, Couturier & Newkirk 1991, Martínez 1991, Pazos et al. 1997), and the effects of maturation on weight and condition index of the adductor muscle are significant. For example, Barber and Blake (1981) have shown that in *A.*

irradians adductor muscle dry weight decreased by two-thirds during maturation. Muscle weight decline has been associated mostly with decreases in muscle glycogen, and on increase in gonad lipids (Comely 1974, Taylor & Venn 1979). A diploid scallop transforming muscle glycogen to lipids theoretically could lose wet weight during maturation without releasing eggs. This is because glycogen can be converted to lipids through lipogenesis in mollusks (Gabbot 1975), but glycogen is stored in a highly hydrated form; for each gram of stored carbohydrates, there are 4 to 5 g of stored water (Randall et al. 1998). In contrast, lipids are accumulated in tissues with very little water. Thus, to produce 1 g of lipid, an organism must use a much larger weight of glycogen. We observed that carbohydrate concentrations were lower in the muscle of diploid organisms in October 2000 and March 2001, whereas lipid concentrations in the gonads increased by the end of the sampling period, as expected for organisms going through gametogenesis-vitellogenesis and previously observed for the same species (Ruiz-Verdugo et al. 2001b). With no difference in carbohydrates and less total proteins and lipids in the gonads of triploid organisms, we might have expected a smaller gonad, but water content in triploid gonads was higher than in diploids, thus contributing to higher total gonad weight. In muscle of triploid scallops, we expect greater muscle weight, with no differences in water and protein and with more carbohydrates and lipids. Thus, greater total and muscle weights in triploid scallops theoretically could be attained without spawning.

In conclusion, triploid sterility increases adductor muscle weight in catarina scallops, through an increase in carbohydrate storage that affects the size of adductor muscle fibers (hypertrophy), which is a result of a lower energy allocation to gonads. Thus, the increase in muscle size in the gigantism hypothesis may be a direct consequence of the energy allocation hypothesis.

AFLP LINKAGE MAP OF AN INTRASPECIFIC CROSS IN *CHLAMYS FARRERI*

SHI WANG, ZHENMIN BAO,* JIE PAN, LINGLING ZHANG, BING YAO, AIBIN ZHAN, KE BI AND QUANQI ZHANG

Laboratory of Marine Genetics and Breeding (MGB), Division of Life Science and Technology, Ocean University of China, Qingdao 266003, People's Republic of China

ABSTRACT Zhikong scallop, *Chlamys farreri*, is the most important species for sea-scallop breeding programs in China. The linkage maps of *C. farreri* were constructed with AFLP markers generated from 21 primer combinations. The polymorphism level of F1 progeny is 62.94%. Of the 783 polymorphic markers detected, 317 segregated in 1:1 ratios and 190 in 3:1 ratios, whereas the other 276 showed segregation distortion ($\alpha = 0.05$). Linkage analysis used the program MAPMAKER/EXP at LOD = 2.5 and $\theta = 0.30$. The male map containing 94 markers in 19 linkage groups, was 1511.4 cM in total length and 66.56% in genome coverage. The female map containing 97 markers in 20 linkage groups, was 1610.2 cM in total length and 66.05% in genome coverage. The distribution of AFLP markers is relatively even in chromosomes of male and female map, because only few of clusters were observed.

KEY WORDS: *Chlamys farreri*, genetic linkage map, AFLP, intraspecific cross, segregation distortion

INTRODUCTION

Genetic linkage maps have become powerful research tools in genetic studies of many species (Saliba-Colombani et al. 2000, Wu et al. 2000, Tan et al. 2001). A saturated linkage map can efficiently carry out molecular-based analyses such as molecular marker-assisted selection (Rance et al. 2001, Kelly et al. 2003), quantitative trait loci (QTL) mapping (Linde et al. 2001, Chen et al. 2001, Mignouna et al. 2002), genetic basis of heterosis (Jones et al. 2003, Hua et al. 2003), and comprehensive investigations of genome evolution (Naruse et al. 2000, Doganlar et al. 2002, Slate et al. 2002).

Although there have been many techniques such as RFLP, RAPD, and SSR available for constructing genetic linkage maps, their applications are limited for various reasons. Amplified fragment length polymorphism (AFLP) is a recently developed marker system that combines the advantages of different marker systems and provides a new opportunity for mapping species with large, but less understood genomes. It can detect a large number of genetic loci per reaction and thus can obtain more genetic information than RFLP and RAPD analysis.

AFLP markers have been widely applied to construct the linkage maps in a variety of economically important species, such as rice (Virk et al. 1998, Zhu et al. 1999), rye (Saal & Wricke 2002), soybean (Keim et al. 1997), chicken (Herbergs et al. 1999, Knorr et al. 1999), silkworm (Tan et al. 2001), tea (Hackett et al. 2000), coffee (Ky et al. 2000), fish (Young et al. 1998, Coimbra et al. 2003), oyster (Yu & Guo 2003), and shrimp (Wilson et al. 2002, Li et al. 2003). AFLP markers have also been successfully applied to important genes mapping such as the scab resistance *Vf* gene in apple (Xu & Korban 2000), the *Lr19* gene for resistance to leaf rust in wheat (Prins et al. 2001), the *rhm* gene for resistance to Southern Corn Leaf Blight in maize (Cai et al. 2003), the powdery mildew resistance gene *Rm1* in grapevine (Pauquet et al. 2001), and the fertility restorer gene *rf4* in sorghum (Wen et al. 2002).

Chlamys farreri belongs to Mollusca, Lamellibranchia, Pteriomorphia, Pterioodae, and Pectinidae and distributes mainly in the northern China, the western Korea, and Japan. It is a diploid with 38 chromosomes (Wang et al. 1990) and is one of the most important aquaculture species in China. It is important to understand

its genome organization by means of molecular markers for genetic studies and breeding purposes. However, till now, a linkage map of *C. farreri* has not been reported. The purpose of this study is to build the first AFLP-based linkage map of *C. farreri*.

MATERIALS AND METHODS

Animal Materials

The mapping population of 51 F1 progeny was derived from a pair mating of *C. farreri*. The parents were sampled from a wild population around Changdao Island, Shandong Province, China. The muscle tissues of the parents were scissored off and stored at -20°C . The F1 progenies were sampled at the swimming trochophore larvae stage (about twenty hours after fertilization) and stored in ethanol at 4°C .

DNA Extraction

The parental DNA was extracted from frozen muscle tissues with phenol/chloroform extraction as described by Sambrook et al. (1989). The F1 larvae were individually collected in PCR tube through micro-operation and then lysed in 10- μL sterile water for about 5 hours to serve as the DNA solution.

AFLP Analysis

AFLP analysis was carried out essentially as described by Vos et al. (1995) with some minor modifications, such as reducing the dosage of the reagents, for AFLP procedure in F1 individuals. The DNA samples were digested with *EcoRI* and *MseI*, then ligated to restriction site-specific adaptors. Preamplification was carried out using adaptor-specific primers with no selective base on each primer. The preamplification product was diluted (20-fold for parents and 10-fold for progeny) and then used in selective amplification. The selective amplification used the primers with three selective bases on each primer. Totally, 21 primer combinations were selected for AFLP analysis.

The products of the selective amplification were separated by polyacrylamide gel electrophoresis at 60 W for 1.5 hours and the bands were detected by silver staining. The electrophoretic images were scanned and then saved in a computer for further analysis.

Scoring of Data and Marker Nomenclature

In preliminary study we found that the bands ranged 50–1500 bp, had good reproducibility, and could unambiguously scored, so only these bands were scored in this study. Two persons scored all these bands independently. The consistent data were used for linkage analysis and scored as dominant markers. Bands present were scored as "1" and absent as "0". Unreliable bands were scored as missing "-".

The AFLP marker names were refereed to the primers used: E followed by two numbers refers to the *EcoRI* primer and M followed by two numbers to the *MseI* primer. Bands were numbered serially in descending order of fragment length; thus the last two

numbers of the AFLP marker code refer to the relative position of the band on the gel.

Segregation Analysis

The inheritance patterns of AFLP bands from parents to offspring in a diploid organism are shown in Table 1. Loci segregating in type 1, 3, 7, and 9 are not informative for mapping since all progeny are identical. Type 2 and 4 can only be scored on the basis of band intensities and were thus excluded due to their low reliability. Only type 5, 6, and 8 containing locus segregation information in the F1 progeny can be used for segregation analysis.

For each marker of all 3 types (type 5, type 6, and type 8).

goodness-of-fit of observed-to-expected allelic ratios was analyzed with χ^2 test ($\alpha = 0.05$). Theoretically all three types should have a binomial distribution (Van der Lee et al. 1997). For type 6 and type 8 markers the probability of band presence in progeny is 0.5 and for type 5 markers, the probability is 0.75. The distribution of the segregation ratios in F1 progeny was used to compare with the expected. The goodness-of-fit of observed-to-expected distribution was also analyzed with χ^2 test ($\alpha = 0.05$).

Linkage Analysis

Type 6 and 8 markers were used to construct separate genetic linkage maps for female and male parents with the software program MAPMAKER/EXP (Whitehead Institute, F2 backcross model). The "error detection" feature was used to recognize the circumstance when an event was more probably the result of error than recombination. This feature avoids map expansion (Cervera et al. 2001). A LOD score of 3.0 and maximum recombination fraction $\theta = 0.30$ were initially set as the linkage threshold for grouping markers. Groups were then analyzed with multipoint mapping functions to define the most likely map orders. Markers that did not significantly depart from Mendelian ratios at $\alpha = 0.05$ level were used in the grouping analysis. Once the framework linkage groups were established, the relatively less stringent criteria (LOD = 2.5 and $\theta = 0.30$) were applied to test whether there were any additional markers or distorted markers that could be mapped to the framework map. Map distance in CentiMorgans was calculated with Kosambi's mapping function. Linkage groups were drawn with the MAPCHART2.1 program.

Map Length and Coverage

Two methods were used to calculate the estimated genome length. First, we calculated the average marker spacing/interval(s) by dividing the total map length by the number of intervals (number of markers minus number of linkage groups). The estimated genome length (G_{el}) was determined by adding 2s to the length of each linkage group to account for chromosome ends (Fishman et al. 2001). Second, an estimated genome length (G_{es}) was calculated by multiplying the length of each linkage group by $(m+1)/(m-1)$, where m is the number of framework markers in each group (Chakravarti et al. 1991). Lastly, the average of the two estimates was used as the estimated genome length (G_e) for *C. farreri*. Observed genome lengths were calculated as the total length considering all markers (G_{oa}). The observed genome coverage C_{oc} was determined by G_{oa}/G_e .

Distribution of AFLP Markers

The distribution of AFLP markers was analyzed from 3 aspects:

First, under the hypothesis that AFLP markers are randomly distributed over a linkage group, a Poisson distribution function was assumed with the average marker number per 10 cM interval (μ) as the expected mean (Saal & Wricke 2002). Any interval on a specific chromosome, where the observed number of AFLP markers exceeded the 99% quantile of the cumulative distribution function, was considered an AFLP cluster.

Second, the AFLP marker distribution was also analyzed by calculating the Pearson correlation coefficient between the number of AFLP markers in the linkage groups and the size of the linkage groups (Yu & Guo 2003). Then t -test was applied to test the significance of correlation coefficient at $\alpha = 0.01$ level.

Figure 1. Representative AFLP polymorphism and segregation pattern for 2 parents and 27 progeny with primer combination E33M58. (M is GeneRuler DNA Ladder Mix; A is type 8 marker; B is type 6 marker; C is type 5 marker; D is type 1, 2, 3, 4 or 7 marker)

Lastly, the mapped AFLP markers were classified according to primer combination for analyzing its distribution among the 21 primer combinations used.

RESULTS

Polymorphism Level of AFLP Markers in *C. farreri*

In total, 1244 bands have been detected, of which 783 were polymorphic, that is, 62.94% polymorphic markers. The polymorphism level of each primer combination is listed in Table 2. Depending on the different primer combinations, the number of bands was counted from 42 to 84 in the range of 50 to 1500 bp. Levels of polymorphism individually ranged from 27.69% for E33M61 to 78.85% for E42M58. A typical amplification profile by E33M58 is shown in Figure 1. For all primer combinations, significant cor-

Figure 2. Segregation ratios of AFLP markers in 51 F1 progeny of *C. farreri*. The number of F1 progeny in which an AFLP marker was found was divided into 13 classes (X-axis). The number of AFLP markers (Y-axis) in each class is shown by bars. Open bars represent type 6 and type 8 markers; solid bars represent type 5 markers. The distribution of presence and absence was compared with the expected binomial distribution (curve in solid line, type 6 and type 8 markers; curve in dashed line, type 5 markers).

relation between the total number of bands and the number of polymorphic bands could be observed ($r = 0.68$, $t = 4.04 > t_{0.01}$).

Segregation Analysis

In the 783 polymorphic markers detected, 257 belonged to type 5, of which 190 segregated in 3:1 ratio and 67 showed segregation distortion ($\alpha = 0.05$). The other 526 belonged to type 6 or 8, that is, were segregated in either the male or the female parent. For the male parent, 165 segregated in a 1:1 ratio showing 37.5% segregation distortion, whereas 152 segregated in a 1:1 ratio showing 41.98% segregation distortion for the female parent.

The distribution of the segregation ratios observed in F1 progeny did not resemble the expected distribution ($\alpha = 0.05$) (Fig. 2). The tendency of 1:1 segregation markers' distribution is similar to the expected distribution. However, compared with the expected distribution, the distribution of 1:1 segregation markers showed homozygote excess in the left and heterozygote excess in the right. For the distribution of 3:1 segregation markers, it shows significant allozygote deficiency compared with the expected distribution.

Linkage Map Construction

Two linkage maps were constructed: one for the male parent, the other for the female parent. The male map consisted of 94 markers in 19 linkage groups that covered 1511.4 cM in length, with a maximum interval of 36.9 cM and an average interval of 20.15 cM (Fig. 3; Table 3). The length of the linkage groups ranged from 3.9 to 265.4 cM and the number of markers varied from 2 to 15 per group.

The female map consisted of 97 markers in 20 linkage groups that covered 1610.2 cM in length, with a maximum interval of 36.9 cM and an average interval of 20.91 cM (Fig. 4; Table 4). The length of the linkage groups ranged from 12.0 to 316.0 cM, and the number of markers varied from 2 to 14 per group.

Map Length and Coverage

As shown in Table 5, the genome lengths estimated by two methods were similar, being 2264.21 cM and 2277.1 cM respectively in male, whereas 2428.81 cM and 2446.6 cM respectively in

16	56.4	3	28.2	30.8
17	14.1	2	14.1	14.1
18	3.9	2	3.9	3.9
19	12.0	2	12.0	12.0
Total	1511.4	94	20.15 ^a	

^a Average of all linked markers.

female. The average of the 2 estimates, 2270.66 cM for male and 2437.7 cM for female, was used as the expected genome length. On the basis of the expected genome lengths, genome coverages of the male and female framework maps were 66.56% and 66.05%, respectively.

Distribution of AFLP Markers

Three clusters were found: two being located on linkage group 2 in male map and one on linkage group 6 in female map. AFLP marker distribution in these regions deviated significantly from the Poisson distribution ($P = 0.01$). The Pearson correlation coefficient analysis (Male: $r = 0.94$, $t = 11.26 > t_{0.01}$, Female: $r = 0.99$, $t = 27.13 > t_{0.01}$) exhibited highly positive correlation between the size of the linkage group and the number of AFLP markers in the linkage group.

The distributions of the AFLP mapping markers among 21 primer combinations were shown in Table 6. The average proportions of markers used for mapping were 35.61% (male) and 37.02% (female), respectively. Most primer combinations generated 5–12 markers that were useful for mapping; but E32M54 and E33M61 generated poorly informative markers for mapping. The numbers of mapped markers among all primer combinations ranged from 2 to 20. Markers generated by any primer combination that were clustered on only one linkage group or in only one region were not found.

DISCUSSION

Polymorphism Level of AFLP Markers in *C. farreri*

The efficiency of constructing a genetic linkage map depends on the heterozygosity level of markers in a species. For *C. farreri*,

its genome should have relatively high heterozygosity because of its mix-mating reproduction system in the nature. In this study, the high polymorphism level (62.94%) as revealed by AFLP markers in the F1 progeny of *C. farreri* reflected high heterozygosity level of the parent genome. The polymorphism level in *C. farreri* based on RAPD markers and isozyme markers is 75.82% and 41.18%, respectively (Song et al. 2002, Li et al. 2001). These results indicate that the heterozygosity level of *C. farreri* is relatively high.

Most of the 21 primer combinations could not only give high polymorphism ratios, but also produce a large number of polymorphic bands. Significant correlation ($r = 0.68$, $t = 4.04 > t_{0.01}$) was found between the total number of bands and the number of polymorphic bands for all primer combinations in the present study, which made it easier to select primer combinations for obtaining highly informative markers.

Segregation Distortion

In this study, segregation distortion ratio is about 35.24% when considering all polymorphic bands in F1 progeny. Segregation distortion ratio is 37.50% (male) and 41.98% (female) when considering 1:1 segregation pattern in either male parent or female parent. Deviations from Mendelian segregation have been reported in constructing genetic linkage maps with molecular markers: 25% of RFLP markers in the soybean (Deshui et al. 1997), and 40% of RAPD markers in the *Medicago* (Jenczewski et al. 1997). Distorted segregation ratios of AFLP markers were also observed: 8.2% in the oyster (Yu & Guo 2003), 14% in the melon (Wang et al. 1997), 32% in the coffee (Ky et al. 2000), 56% in the silkworm (Tan et al. 2001), and 65% in the clubroot (Voorrips et al. 1997). Distorted segregation of molecular markers may result from sampling in finite mapping populations, preferential fertilization, breaking of DNA chains during extraction of DNA samples from tissues, or amplification of a single-sized fragment derived from several different regions (Tan et al. 2001). The above explanations cannot account for the relatively high-distorted segregation in this study. Deviation from Mendelian segregation ratios in bivalves grow more severe as progeny age (Gaffney & Stott 1984), which may result from natural selection against recessive deleterious genes (Launey & Hedgecock 2001). The distribution of 1:1 and 3:1 segregation markers observed in *C. farreri* in this study did not resemble the expected distribution (see Fig. 2) and the fact of significant allozygote deficiency support the hypothesis. Genetic map also provides an efficient approach to investigate the cause of segregation distortion. In this study, the skewed markers assembled together in specific regions of only a few linkage groups, which not only corresponds with the hypothesis but also implies that the specific regions may contain genes influencing the development of the early larvae. Mapping the skewed markers may have little effect on estimating the recombination frequency (Hackett & Broadfoot 2003) but can provide useful information for genetic research and breeding in *C. farreri*, so our final genetic maps include these markers.

Genetic Mapping of AFLPs in *C. farreri*

The haploid genome of *C. farreri* contains 19 chromosomes (Wang et al. 1990). Our male genetic map is composed of 19 linkage groups and female genetic map is composed of 20 linkage groups. Nonequivalence between the number of linkage groups

Figure 4. Genetic linkage maps of the female *C. farreri*. (The symbols are the same as in male map)

and the number of chromosomes has also been reported in other studies (Young et al. 1998, Vivek & Simon 1999). It is difficult to construct maps without missing some chromosomes for species with large number of chromosomes in haploid genomes (Yasukochi 1998), especially when the total number of markers and the coverage are not large enough.

Our AFLP map with an average of 20.15 cM (male) and 20.91 cM (female) per interval was not particularly dense. About 64.39% markers in male and 62.98% in female that show Mendelian segregation were not linked in our maps. Higher proportions of unlinked markers were observed in mapping studies in other species (Grattapaglia & Sederoff 1994). However, these markers may be linked when more markers obtained from other AFLP, RFLP, RAPD, and microsatellite analyses were used to construct denser maps.

Map Length and Coverage

The study provides estimated genetic map length for male and female of *C. farreri* for the first. The male map length is 98.8 cM shorter than the female map length, which may reflect sex-specific recombination rates in *C. farreri*. Similar differences have been noted in aquatic animals including rainbow trout (Sakamoto et al. 2000), zebrafish (Knapik et al. 1998), and Pacific oyster (Yu &

Guo 2003). Several possible explanations, such as time spent in meiotic prophase in one sex, transcriptional activity of certain genes during meiosis in one sex, and presence of sequences that are recognized by sex-specific enzymes (Coimbra et al. 2003), have been applied to explaining the phenomenon. So far, the genetic mechanism of suppression in recombination is not yet clear, and there is no adequate explanation for the difference in recombination rate between the two sexes in *C. farreri*.

The map coverage in the *C. farreri* was 66.56% in male and 66.05% in female. The current map coverage is not high compared with other species. To obtain a saturated genetic map in *C. farreri*, effective resolution is not only to integrate the male and female maps but also to add genetic markers obtained from RFLP, RAPD, EST, and microsatellite analyses as well as isozyme loci into current genetic map.

Distribution of AFLP Markers

The distribution of AFLP markers is relatively even in chromosomes of male and female map, because only few of clusters were observed. The number of AFLP markers in the linkage groups that had high positive correlation with the size of the linkage groups also supports this conclusion. In published literature, AFLP markers distribute randomly in some species (Castiglioni et

TABLE 4.

Length, number of markers, average spacing, and largest intervals of linkage groups in the female of *C. farreri*.

Linkage Group	Length (cM)	Number of Markers	Average Interval (cM)	Largest Interval (cM)

al. 1999, Remington et al. 1999, Cervera et al. 2001), but they form cluster in others (Young et al. 1998, Waldbieser et al. 2001, Sakamoto et al. 2000). Some studies suggest the presence of AT-rich sequence blocks, which are more likely to be recognized by *EcoRI* and *MseI* in connection with suppressed recombination even though such distinct AT-rich regions are not in the centromeric and pericentromeric parts.

Analysis of the distributions of informative markers among primer combinations indicated that neither all primers nor all primer combinations could produce informative polymorphic markers for mapping (see Table 6). This suggests that, similar to the RAPD technique, AFLP analysis of the whole genome such as performed here need to search for primer combinations with highly informative markers.

Applicability of AFLPs in *C. farreri* Genetics and Breeding

Genomic mapping provides a new approach to the identification of genes that control commercially important traits (Dudley

^a A is the number of mapping markers.

^b B is the number of markers segregating in male or female parent.

1993). AFLPs have the potential to efficiently and rapidly construct high-resolution maps, which will make gene isolation more convenient. The identification and isolation of specific markers closely linked with desirable traits is necessary for marker-assisted breeding. Also, the comparison of genetic maps from different species or genera can provide insights into animal evolution and genome structure (Hohmann et al. 1995).

However, AFLP markers, especially the gel-based, are difficult to transfer among laboratories and populations, which limits the extension of the AFLP maps' application. In some cases, poor transferability can be compensated for by the ease of developing a large set of AFLP markers in any population of interest, thus limiting the need for transfer (Yu & Guo 2003). Microsatellite markers are better markers for linkage mapping than AFLP markers, because of high levels of polymorphism, codominance, and good transferability. At present, our laboratory is developing a set of microsatellite markers in *C. farreri*. In the near future, these microsatellite markers will be contained in the linkage maps, which will enhance the transferability of the current maps.

ACKNOWLEDGMENTS

The authors thank Prof. Guanpin Yang and Dr. Jingjie Hu for reviewing this manuscript. This work is mainly supported by grants 2002AA628110 and 2003AA603022 from Hi-Tech Research and Development Program of China; G1999012009 from "973" Program of China; 30300268 from National Natural Science Foundation of China; 01BS10 from Outstanding Scientists Research Foundation of Shandong Province.

HYBRIDIZATION EFFECTS OF THREE POPULATIONS OF *CHLAMYS FARRERI* FROM CHINA, KOREA AND JAPAN

LIU XIAOLIN,^{1,3} CHANG YAQING,² XIANG JIANHAI^{1,*}

¹Academy of Sciences, Qingdao 266071, China; ²Key Lab of Marine Ecology in Aquaculture of Ministry of Agriculture, Dalian Fisheries University, Dalian 116023, China; ³College of Animal Technology and University, Northwest Sci.-Tech. University of Agriculture and Forestry, Yangling, Shaanxi 712100, China

ABSTRACT Populations of *Chlamys farreri* are distributed along the coasts of the northern seacoast of China, the Korean Peninsula and the Pacific seacoast, Japan. These populations represent potentially different genetic resources in their production traits important to aquaculture and for their contribution to hybridization breeding programs. To determine their characteristics, crosses between and within three populations of Zhikong scallop, *Chlamys farreri*, were made (Chinese culture population [CC] female × Japanese wild population [JW] male, Japanese wild population [JW] female × Chinese culture population [CC] male, Chinese culture population [CC] female × Korean wild population [KW] male, Japanese wild population [JW] female × Korean wild population [KW] male) and the offspring reared to 24 months of age. Nine consecutive measurements, approximately 60 days apart, were recorded on wet body weight and shell length, width and height. The phenotypic and heterotic response of each sample for growth and survival were compared. The results indicated that there existed positive though varying degrees of heterosis for growth in wet body weight, shell length, shell height, shell width, and survival. Also, there were measurable differences among the reciprocal crosses in their performance traits. The results of this study suggest that hybridization is an important tool to increase the performance and fitness (survival) of cultured scallops.

KEY WORDS: *Chlamys farreri*, hybrid, geographic population, growth, heterosis, hybrid vigor

INTRODUCTION

Chlamys farreri (Jones et Preston), *Chlamys* Roding, *Pectinidae*, *Pterioidea*, *Bivalvia*, *Mollusca* is distributed along the coast of Northern China, the coast of Southern Korea and Northern Korea, the coast of Japan, and the coast of Eastern Russia, it is also widely distributed around the sea area of Shandong province and Liaoning province in China (Pan et al. 2002). The first batch of seedlings were triumphantly cultivated in Dalian, Liaoning province in 1974, and intensively cultured in China where the scallop industry has grown rapidly over the last 20 years. The cultured area has reached 400,000 μ and production yield of 919,591 tons; tip-top yield reached more than one million tons, and *Chlamys farreri* culture is one of the three mainstay mariculture industries in China, which is now one of the top producers of cultured scallop in the world (Xiang 2002). *Chlamys farreri* grow relatively slow (1.5–2 y to market size of 6–8 cm). The primary problem of *Chlamys farreri* culture is cosmically death because of the decline of the idioplasm and disease resistance (Wang et al. 2002). To overcome the obstacle, the new breeding method, especially crossbreeding should be applied.

Technologic developments have made hatchery production of scallop's feasible (Castagna & Duggan 1971, Gruffydd & Beaumont 1972). The scallop species, *Chlamys farreri*, has become an important aquaculture species along the coast of northern China with the first hatchery production of seedling scallops in the 1970s (Wang 1981). However, seedling quality (idioplasm) degeneration and fitness depression have become major technical obstacles to intensive hatchery production of scallops.

Inter-species and intra-specific hybridization has received attention from researchers in aquaculture because it can improve

productivity through hybrid vigor and combine desirable characteristics found in one species with those of another (or in one population with those of another). Experimental attempts to produce inter-species hybrids in the oyster, the scallop, and the hard clam have reported few successes. It has been reported that spawn rate, hatch rate, and the survival of hybrid progeny to post-larval stages are low compared with the intra-specific matings and then some inter-species hybrids are sterile (Hedgecock 1987, Longwell 1987, Menzel 1987, Xiang & Chen 1991, Ouang & Liu 1959, Clark & Talbot 1973, Ke & Tian 2000, Leighton & Lewis 1982, Zhou & Gao 1982).

Intra-specific hybrids can produce heterosis and combine desirable characteristics to improve productivity because different populations represent potentially different genetic resources (Manzi & Hadley 1991, Newkirk & Waugh 1977, Newkirk 1978, Mallet & Haley 1983, Stiles 1978, Bower & Blackburn 1997, Cruz & Ibarra 1997, Chevassus 1983).

The purpose of this study is to investigate population differences and heterosis in growth traits and survival among three samples taken from Chinese, Japanese and Korean populations of the Zhikong scallop, *Chlamys farreri*. The population samples were mated to produce pure and reciprocal cross progeny.

MATERIALS AND METHODS

Collection and Maintenance

The sample of the Chinese scallop (CC) was collected from the cultured population in Dalian Bay, Dalian City, Liaoning province (north latitude 38°42'N, east longitude 121°31'E, and annual temperature range 1.0–22.8°C). The sample of the Korean scallop (KW) was collected from a wild population on the sea coast of Korea (north latitude 35°28'N, east longitude 130°28'E, and annual temperature range 4.5–23.7°C). The sample of the Japanese scallop (JW), also from a wild population, was collected from the Pacific seacoast of Japan (north latitude 40°52'N, east longitude 142°22'E, annual temperature range 2.5–21.6°C. Each sample was

held for half year in a maturation unit prior to mating. The diet consisted of fresh *Isochrysis zhanjiangensis* and *Platymonas* sp.

Experimental Design and Cross-fertilization

Fertilization between and within the three population samples were conducted at room temperature (19–21°C): CC male × CC female, JW male × CC female, KW male × CC female, CC male × JW female, JW male × JW female, KW male × JW female. Only male scallops were included in the sample taken from the KW population. Thus, the within and cross genotype fertilizations involving KW females are not included in this study because of no female spawning eggs.

A random sample of 80–100 adult *Chlamys farreri* individuals (7–10 cm length) from each of the three populations were taken for spawning. Each sample was dried in the shade for 2 hours and placed in a separate container filled with UV-sterilized filtered seawater to collect sperm and ovum. Fertilization was accomplished through mixing of the diluted sperm and diluted ovum containers. After 2–4 hours the sperm-ovum mixture was rinsed in seawater two to three times and incubated in seawater in 100-L plastic tanks at room temperature.

Larval and Juvenile Rearing

Larvae were reared on a diet of mixed algae, *Isochrysis zhanjiangensis* and *Platymonas* sp. All cultures were carried out in filtered seawater (FSW) at 19–23°C, the approximate ambient seawater temperature. Each day 50% to 75% of the culture water was removed by reverse filtration/siphoning and replaced with fresh FSW. Fresh air was continuously pumped into each culture.

Culture of Adults

After 2 months of age the cultured juveniles from each group were placed separately into plastic cages and suspended in the sea. Body weight and shell height and width and length measurements were recorded every 2–3 months, when the cages were changed, until 24 months of age.

Measurement Date

Although the experimental design called for weight and linear measurements to be recorded at 60-day intervals, weather conditions and workload sometimes precluded doing this.

Measurement and Statistical Analyses

From each progeny subclass 100–150 offspring were sampled for measurements of body size (shell length, S-L; shell height, S-H; shell width, S-W) and body weight (B-W) at approximately 2-month intervals. Within each test period the percent heterosis (H) of each cross was computed as:

$$H(\%) = \frac{F_1 - \frac{1}{2}(P_1 + P_2)}{\frac{1}{2}(P_1 + P_2)} \times 100 \quad (1)$$

where, F_1 , P_1 , P_2 represent trait average of the first generation cross, parent 1 and parent 2, respectively. Incremental change (G) in body weight and in each linear measurement for each period was computed as:

$$G = (W_2 - W_1)/(t_2 - t_1), \quad (2)$$

where t_1 and t_2 represent time at the beginning and end of each period and W_1 and W_2 represent the menstruation value at the beginning and end of each period.

RESULTS

Comparison of Heterosis of Different Crossbred for Different Characters in Each Period

The average and standard deviation of each progeny group for body weight and linear measurement, including calculated heterosis for the reciprocal crossbred samples CC × JW and JW × CC, for each test period are included in Table 1. The Chinese cultured population has similar body weight growth, as does the Japanese wild population. Across the nine measurement intervals the F_1 hybrid progeny of three *Chlamys farreri* samples exhibited a wide range of heterosis, from 4% to 50% (see Table 1). Among the F_1 progeny the JW × KW cross exhibited the most heterosis followed by the CC × KW, JW × CC, and CC × JW crosses. Among the growth traits there were distinct differences in the magnitude of heterosis expression. Shell height tended to be more heterotic than shell length followed by shell width and wet weight. The expression of heterosis in each trait tended to decrease as age of the scallop increased.

In this study the F_1 hybrid combinations exhibited satisfactory levels of heterosis over the nine evaluation periods. The JW female × KW male and CC female × KW male F_1 were the optimal crosses, than can be applied in aquaculture production.

Comparison of the Growth Rate for Four Hybrids and the Purebred

The means (δ , ccm/d, and mg/d) for growth rate of shell length, width, and height and for body weight by age in months for the CC and JW parental samples and four F_1 progeny samples are included in Figure 1.

Growth rate for each trait in each sample reached its pinnacle at 13 months of age. The incremental changes in growth were greater for each trait in each hybrid sample than in the pure parental samples.

The Growth Trend of Chlamys Farreri for Different Characters for Four Hybrids and the Offspring of Pure Parents by Age in Months

Based on the serial measurements of wet weight and shell length increase in parental and F_1 sample of *Chlamys farreri*, growth differences among the parental and F_1 progeny samples were evaluated (Fig. 2).

The growth in shell length tends to plateau at approximately 16 months of age. The growth curve for both wet weight and shell length was greater in the F_1 progeny samples than in the pure parental samples. Among the F_1 progeny samples, the growth curve for wet weight and shell length tended to be different.

Comparison of Growth at 24 Months of Age for Three Hybrids and the Offspring of Their Parental Populations

At 24 months of age the wet weight of the F_1 progeny samples was heavier than their pure parental samples (see Fig. 2 A). Much of the difference between the F_1 progeny and their parental pure counterparts can be attributed to heterosis. Wet weight is the most important trait in scallop production and hybridization can be a useful tool in improving wet weight growth. However, not all F_1 combinations result in equal growth in wet weight. Therefore, experimental evaluation of crosses between sampled populations

becomes a necessary precondition to include hybridization of populations in commercial scallop culturing. Figure 2 B includes the differences at 24 months of age among the F₁ and parental pure progeny samples for shell length. The shell length of the F₁ samples was much greater than those of the parental populations. As was the case for wet weight, heterosis was an important part of the increase in shell length in the F₁ progeny samples.

DISCUSSION

Comparison of the Survival for Four Hybrids and the Offspring of Two Parent Populations

The percentage of survival from the zygotes to juveniles of 2 months of age for four hybrids and the offspring of two parent populations were calculated in Table 1. The percentage of survival for four hybrids were significantly greater than the purebred ($P < 0.05$), and the percentage of survival for Chinese purebred was

significantly greater than that of Japanese purebred, there were no significant differences of survival percentage among the four ($P > 0.05$).

Comparison of the Growth for Three Hybrids and the Offspring of Three Parent Populations

Our evaluation of four phenotypic traits, shell length, shell width, shell height and body weight, suggest genetic differences among two scallop populations and their reciprocal F₁ crosses evaluated simultaneously under the same environmental conditions. From age 5 months to 24 months, there were differences in body weight and shell linear sizes over the sampling period. The samples from the Chinese cultured population and the Japanese wild population were similar, but crossbred offspring were consistently faster ($P < 0.05$) growing than purebred offspring (see Table 1).

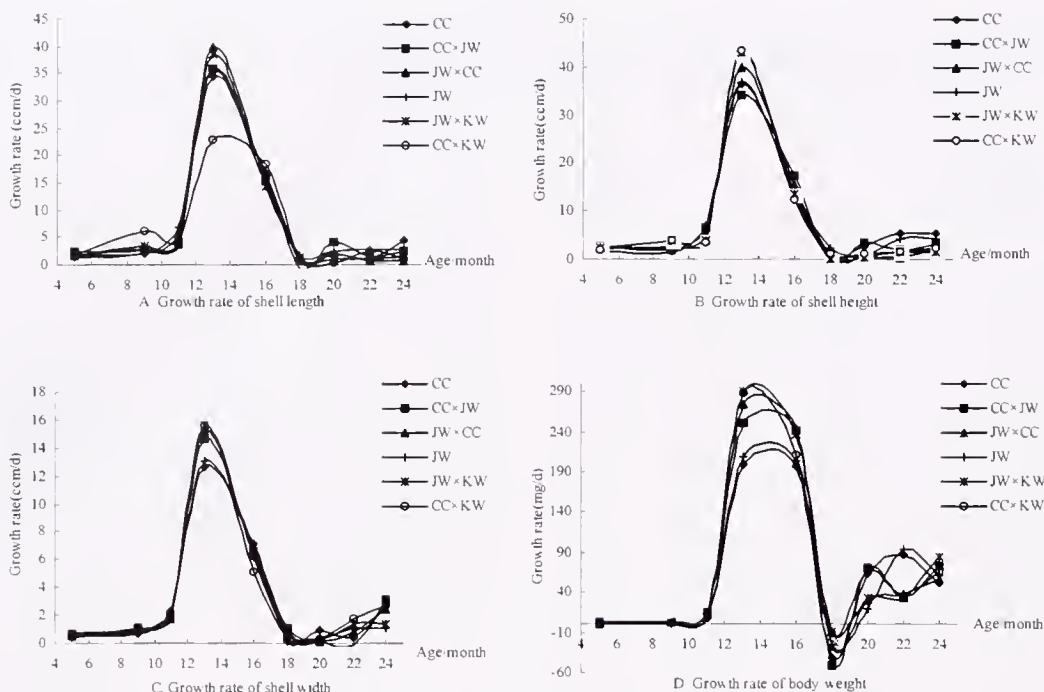

Figure 1. Comparison of growth rate of four characters for four hybrid stocks and their parental populations, (A) growth rate of shell length; (B) growth rate of shell height; (C) growth rate of shell width; and (D) growth rate of body weight.

Comparison of the Growth Among the Different Periods

The growth rates for each of the four phenotypic traits included in this study are influenced by seasonal environmental conditions. During winter months the cold water causes the growth rate of scallops to approach zero or even lose body weight and size. However, during the warmer seasons of summer and fall growth rate rapidly increases.

Comparison Among the Growth Rate of Four Phenotypic Traits Over the Evaluation Period

The growth rates of each of the four phenotypic traits, shell length, shell width, shell height, and body weight tend to be different. Among these traits body weight growth is the fastest fol-

lowed by shell length, shell width, and shell height. Therefore, among the linear shell measurements the shell length should be the most important selection trait in a breeding program.

Breeding and Heterosis Utilization of *Chlamys Farreri*

Scallop breeding has received considerable research attention because the development of aquaculture has increased. Developments in artificial insemination and juvenile rearing techniques have succeeded in improving the efficiency of scallop culturing. However, performance of the economic traits and purity of the cultural stocks have been reduced because of the idioplasm retrogression and the parental scallops are wild populations. Thus, it is difficult to expect stable levels of heterosis. Selective breeding and evaluation of new breeds and strains are the bases of the hybridization breeding programs. Such breeding programs can provide

Figure 2. Cumulate growth comparison of Chinese and Japanese populations with four populations of hybrids, (A) cumulate growth of body weight and (B) cumulate growth of shell length.

pure hybridization parents and overcome the idioplasm retrogression. The research reported here shows that for wet shell weight and linear shell measurements in crosses among cultured and wild

populations of the *Chlamys farreri* scallop, positive heterosis are expressed at levels sufficient to warrant systematic hybridization in the culture of scallops.

LIPID CLASSES AND FATTY ACID COMPOSITION IN FEMALE GONADS OF GREAT SCALLOPS—A SELECTIVE FIELD STUDY

ARNE DUINKER,* BENTE E. TORSTENSEN, AND OYVIND LIE

National Institute of Nutrition and Seafood Research, PO Box 176 Sentrum, 5804 Bergen, Norway

ABSTRACT Fatty acid composition was analyzed in neutral lipids (NL), phosphatidyletanolamine (PE) and phosphatidylcholine (PC) of *Pecten maximus* (L.) ovaries from Western Norway. Individual ovaries were selected based on macroscopic characterization. Two series were compared; (1) ovary development from recovering to half-full ovaries during the autumnal restoration of the gonads and (2) seasonal variation with late filling ovaries from different parts of the year. The relative lipid content and the proportion of triacylglycerols increased during development. Changes in fatty acid composition during ovary development were minor compared with the changes observed with seasonal variation. The samples from June differed from the other samples with a large increase in 20:5n-3 on the expense of 22:6n-3 in neutral lipids (NL) and phosphatidylcholine (PC) and a concomitant increase in 20:5n-3 and 22:6n-3 in phosphatidyletanolamine (PE). The changes in NL and PC can probably be attributed to a dietary effect from the diatom dominated spring phytoplankton bloom. Only small changes in the degree of unsaturation in PC were seen that may be due to a temperature effect. The differences observed represent large differences in status of broodstock from field prior to conditioning in season independent hatchery production.

KEY WORDS Fatty acids, lipid composition, ovaries, *Pecten maximus*, phospholipids, scallops, triacylglycerols

INTRODUCTION

The importance of lipids for the quality of eggs and larvae of bivalves is well established. Broodstock diet in particular influences the lipid composition in the gonads and eggs (Helm et al. 1991, Utting & Doyou 1992, Soudant et al. 1996a, Soudant et al. 1996b, Soudant et al. 1996c, Soudant et al. 1999). Special attention has been given to the polyunsaturated fatty acids 22:6n-3, 20:4n-6 and to a lesser but still important extent 20:5n-3. These are selectively incorporated in the phospholipids during gonad build up, despite deficiencies in diet (Soudant et al. 1996a). Lipid composition of the ovaries and eggs then affects larval performance. 22:6n-3 has been demonstrated as essential for growth and survival of bivalves (Langdon & Waldo 1981). Higher levels of 22:6n-3 and a higher 22:6n-3/20:5n-3 ratio were associated with improved hatching rate and enhanced gametogenesis in *Pecten maximus* (Soudant et al. 1996a, Soudant et al. 1996b), while growth rate was significantly related to the content of 22:6n-3 in oyster larvae (Thompson & Harrison 1992, Berntsson et al. 1997). Another factor known to influence membrane lipid composition in poikilotherms is temperature. Lipid class and fatty acid composition is regulated according to the temperature to maintain optimal fluidity of the membranes (Williams & Hazel 1994), and dietary input of essential fatty acids may be required for cold acclimation (Farkas et al. 1980). Increased unsaturation of the phospholipids or increase in sterol content at low temperatures is also reported for bivalves (Ueda 1974, Piretti et al. 1988, Chu & Greaves 1991, Napolitano et al. 1992).

Seasonal changes in lipid composition of ovaries have been reported in several studies of scallops (Besnard et al. 1989, Napolitano & Ackman 1992, Pazos et al. 1997). Changes in lipid composition have been related to reproductive activity, but the effects of season and stage of maturity have not been separated. Scallops in the field experience large fluctuations in food composition from various phytoplankton blooms, known to differ in fatty acid composition (Budge et al. 2001) which gives imprints in filter feeders (Pedersen et al. 1999, Shirai et al. 2002). Temperature

fluctuations in the field can also affect lipid composition of bivalves (Ueda 1974, Piretti et al. 1988). In seasonal independent hatchery production of *P. maximus* in Norway, broodstock animals are taken from the sea for conditioning in the hatchery at different times of the year. Variations in lipid composition of animals from the field will hence represent differences in status prior to conditioning.

Field data are often important basis for evaluating the quality of artificial conditioning and other aquacultural manipulations (e.g. Soudant et al. 1999). A study was performed to describe variations in lipid composition in ovaries from a *P. maximus* field population. From a parallel study, large variations in ovary developmental stages were seen during the reproductive cycle of this population (Duinker & Nylund 2002). Individual ovaries were therefore selected based on macroscopic characteristics of ovary development, to get a more precise description of lipid composition in the different ovary developmental stages than a population average would have given. Two series of ovaries were selected, one consisting of ovaries in the same stage of development from different times of the year, and one with successive developmental stages during the autumn restoration of the gonads. The aim of this study is to compare seasonal variations in lipid class and fatty acid composition with the variations during development.

MATERIALS AND METHODS

Sampling Procedures

Individual ovaries were sampled monthly in combination with studies of seasonal variation in chemical composition of ovaries and storage organs in *Pecten maximus* (Strohmeier et al. 2000) and histologic and visual characterizations of the ovaries (Duinker & Nylund 2002). The scallops were collected in Raunefjorden south of Bergen, Norway, and ovary samples were stored at -80°C . Ovaries were selected based on visual characterization as described by Duinker & Nylund (2002). The characterization is based on the study of Mason (1958), and the stages sampled for ovary development were (numerical values in brackets): "recovering" (3), "filling" (4), "late filling" (4.5), and "half full" (5). These ovaries were sampled on September 15, October 18, December 12, 1997, and February 7, 1998, respectively (Table 1).

The numbers represent the ovary development stages recovering, (3); filling, (4); late filling, (4.5); and half full, (5).

Filling (4) ovaries from February 15, 1997 and half-full (5) ovaries from March 12, 1997 were sampled as spring controls for comparison with the corresponding stages sampled during autumn. Only changes that were consistent between the samples in both series were considered as related to ovary development. Late filling (4.5) ovaries were selected for seasonal variation from the March 31, June 8, December 12, 1997, and February 7, 1998 samples. The samples for the late filling stage in the ovary development series and the seasonal variation sample from December were identical.

Analytical Procedures

The ovary samples were freeze-dried and dry weight percentage was determined. After homogenizing the samples, lipids were

extracted with chloroform-methanol (2:1, v/v), modified from Bligh and Dyer (1959) according to Ronnestad et al. (1995), and total lipid content was determined gravimetrically. Further, lipid classes were separated by HPLC as described by Lie and Lambertsen (1991) using a Constametric II solvent-delivery system at 205 nm with a variable-wavelength spectrophotometer (LDC Spectromonitor III). The column (25 cm \times 0.46 cm I.D.) was packed with silica gel (LiChrosorb 5 μ m, Merck). The initial solvent mixture consisted of hexane:2-propanol:acetonitrile (4:3:7, v/v/v). This was added to the protocol of Lie & Lambertsen (1991) and eluted two unidentified peaks¹, whereas NL eluted with the front. The second solvent mixture of hexane:2-propanol:acetonitrile: water (372:496:97:35, by volume) eluted PE. PC was eluted with hexane-2-propanol-water (394:526:80, v/v/v). The identity of the isolated phospholipids was checked by TLC (Kiesel-gel 60 Merck), using phospholipid standards and a solvent system of ethyl acetate-n-propanol-chloroform-methanol-0.25% aqueous KCl (15:25:25:10:4.5, by volume).

The three fractions were collected manually into vials, saponified, and esterified in 12% BF₃ in methanol, and the fatty acid composition of the different lipid classes was determined according to Lie and Lambertsen (1991). The methyl esters were separated using a Carlo Erba gas chromatograph ("cold on column" injection, 60°C for 1 min at 25°C min⁻¹, 160°C for 28 min at 25°C min⁻¹, 190°C for 17 min at 25°C min⁻¹, 220°C for 2 min), equipped with a 50-m CP-sil 88 (Chromopack) fused silica capillary column (i.d. 0.32 mm, 0.20- μ m film) (Lie & Lambertsen 1991). The fatty acid composition was calculated using an integrator (Turbochrom Navigator, Version 6.1), connected to the GC and identification ascertained by standard mixtures of methyl esters (Nu-Chek, Elyian, USA). The quantification of lipid classes in

¹One peak was rich in 22:6n-3 and the other was rich in 20:4n-6. These were eluted similarly as the fraction earlier assumed to be a glycolipid (Soudant et al. 1995), now identified as cardiolipin (Kraffe et al. 2002). The two peaks were only separable using new columns in the present set-up. They were not identified and are thus not reported here.

Figure 1. Lipid content (g) per ovary (dotted line, left axis) and mg lipid per 100 g tissue dry weight (solid line, right axis). Vertical bars indicate standard deviations, $n = 3$.

recovering (3) and half-full (5) ovaries was performed using high-performance thin-layer chromatography (HPTLC) as described by Bell et al. (1993). Total lipid (10 µg) was applied to a 10 × 20 cm HPTLC plate that had been prerun in hexane:diethyl ether (1:1 v/v) and activated at 110°C for 30 min. The plates were developed at 5.5 cm in methyl acetate: isopropanol: chloroform: methanol: 0.25% (w/v) aqueous KCl (25:25:25:10:9, by volume) to separate phospholipid classes with neutral lipids running at the solvent front (Vitello & Zanetta 1978). After drying, the plates were developed fully in hexane: diethyl ether: acetic acid (80:20:2, v/v/v) to separate neutral lipids and cholesterol. Lipid classes were visualized by charring at 160°C for 15 min after spraying with 3% copper acetate (w/v) in 8% (v/v) phosphoric acid identified by comparison with commercially available standards. Lipid classes were quantified by scanning densitometry using a CAMAG TLC Scanner 3 and calculated using an integrator (WinCATS-Planar Chromatography, Version 1.2.0).

Statistics

The data for fatty acid composition in the lipid classes of recovering (3) and half-full (5) ovaries were compared using the Mann-Whitney test (Zar 1999). With the low *n* of three individuals per point these statistics are only used as guidance for interpreting the results. The relative fatty acid composition data of the lipid classes was analyzed using SIRIUS for Windows (Pattern recognition systems AS, Norway, Version 6.0). Principal component analysis (PCA) (Wold et al. 1987) was performed in the data matrix of the relative fatty acid compositions. The purpose of PCA is to express the main information in the variables by a lower number of variables, the so-called principal components (PC1, PC2, ...). A high positive or negative loading reveals a significant variable in the actual PCA model. Score plots from the PCA explore the main trends in the data, and their respective loading reveal fatty acids with a significant loading. Basically, samples or variables with a similar angle from origin in the score and loading plots, respectively, are positively correlated. A 90° angle reflects no correlation and towards 180° reflects negative correlation. Variables (fatty acids) and samples can be compared in the same way, so that samples are positively influenced by variables with a similar angle from origin and so on.

RESULTS

The relative lipid content of dry weight in the ovaries increased linearly 2.6-fold during development from recovering (3) to half-full (5) ovaries. In contrast, there was no variation in relative lipid content throughout the season (Fig. 1). Total content of lipid per ovary increased 10-fold during development, whereas only some variation due to different sizes of the gonads were seen in the samples for seasonal variation, with no clear trends (see Fig. 1). Triacylglycerols (TAG) increased from 32% in recovering ovaries to 47% in half-full ovaries concomitant with a corresponding decrease in phospholipids (PL) and cholesterol (Fig. 2a). This corresponds to an increase in neutral lipids from 46% to 61% if only fatty acid containing classes are quantified, hence omitting cholesterol and adding up TAG and free fatty acids (FFA). Within the PL, only marginal differences were seen when comparing recovering (3) and half-full (5) ovaries (see Fig. 2b).

Multivariate principal component analysis (PCA) of the relative fatty acid composition of the neutral lipids (NL), phosphatidylcholine (PC) and phosphatidylethanolamine (PE) showed that

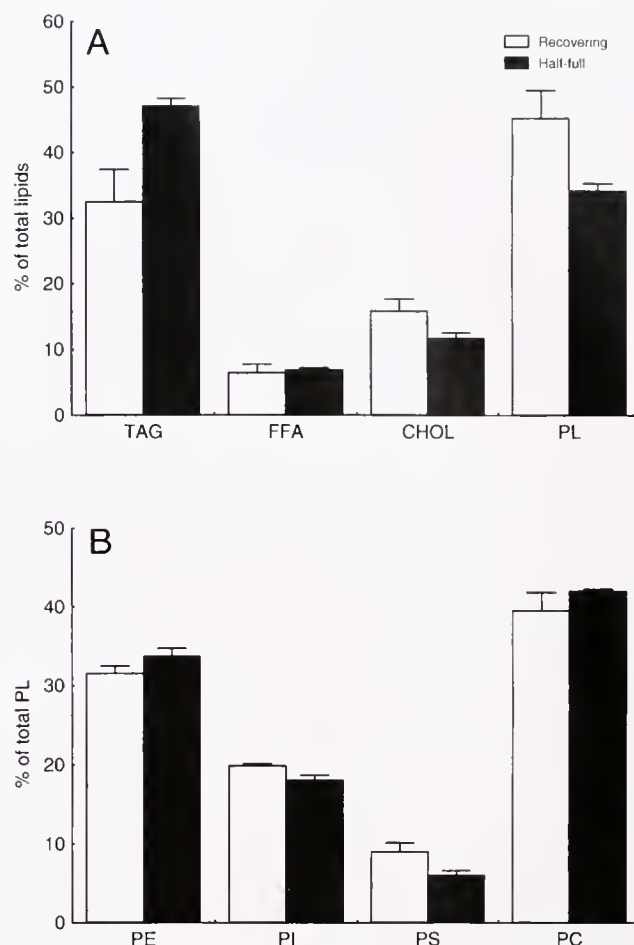

Figure 2. Relative lipid class composition in recovering (3) and half-full (5) ovaries sampled September 15, 1997 and February 7, 1998 respectively. A. Neutral lipids (TAG, triacylglycerids, FFA, free fatty acids; CHOL, cholesterol) vs. total phospholipids (PL) as percent of total lipids. B. The phospholipid classes phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidylserine (PS) and phosphatidylcholine (PC), as percent of total phospholipids. Vertical bars indicate standard deviations, *n* = 3.

each of the lipid classes analyzed has its characteristic fatty acid composition and are separated in the score plot (Fig. 3). The variables 22:6*n*-3 and 16:0 had high positive loadings along PC2, whereas 18:0 and 20:5*n*-3 had high negative loadings along PC2. Further, 22:6*n*-3 and 18:0 had high negative loadings along PC1, and 16:0 and 18:4*n*-3 had high positive loadings along PC1. These loadings correspond to the grouping of the PC, PE, and NL samples with PC containing high levels of 22:6*n*-3 followed by PE and NL. Furthermore, NL contained high levels of 18:4*n*-3 and lower levels of 22:6*n*-3 compared with the phospholipid classes. The level of 20:5*n*-3 was highest in PE; 16:0 was the dominant saturated fatty acid in PC whereas 18:0 was dominant in PE (see Fig. 3). During development, 20:5*n*-3 increased 1.6 fold, 1.5-fold and 1.9-fold in NL, PE and PC, respectively (Fig. 4 and Table 2). The main increase was between the recovering (3) and filling (4) stages. During development, 22:6*n*-3 decreased slightly in NL, increased 1.3 fold in PE and showed no variance of significance in PC. The largest differences in fatty acid composition, however, were seen in ovaries from June compared with the other samples for seasonal variation. In June 20:5*n*-3 was markedly higher on the

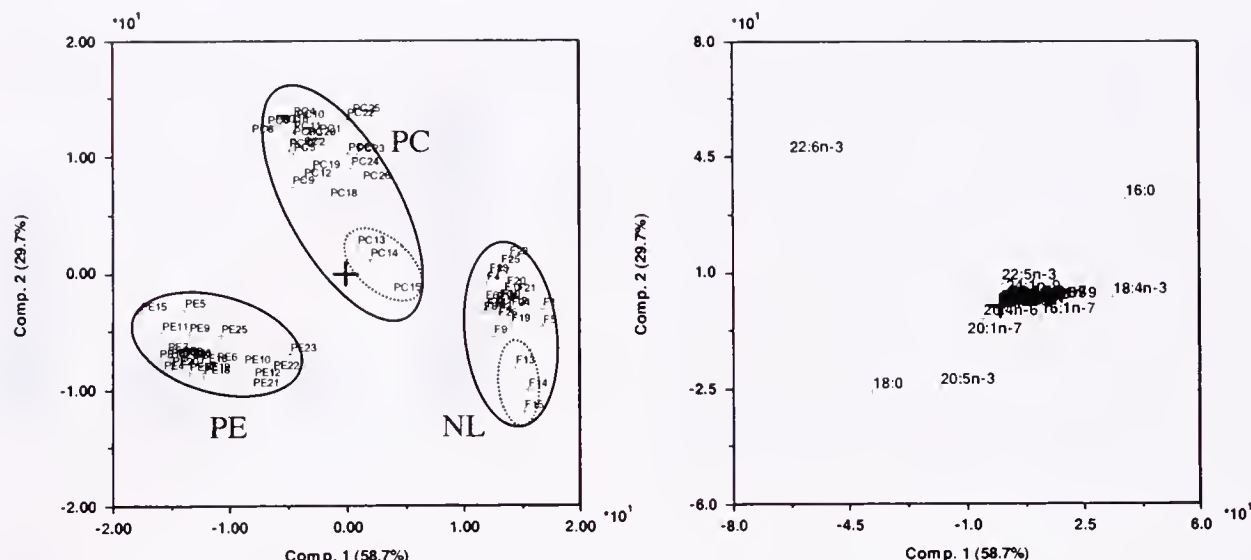

Figure 3. Separation of the different lipid classes (encircled by hand) according to their fatty acid composition using multivariate principal component analysis. The samples from June are encircled with a dotted line in PC and NL.

expense of 22:6n-3 in NL and PC (see Fig. 4), while both 20:5n-3 and 22:6n-3 were higher in PE. This shift resulted in a decrease in the 22:6n-3/20:5n-3 ratio between the other samples and June from 2.7 to 1 in PC and 1.2 to 0.5 in NL, while the ratio was relatively stable in PE.

The ratio of polyunsaturated/saturated fatty acids showed some differences with season in PC, though values from December overlapped with values from February. The ratio was higher in March (3.1) and February (2.8), compared with June (2.6) and December (2.5). The concurrent increase in 20:5n-3 and 22:6n-3 in June lead to higher ratio of polyunsaturated/saturated fatty acids in PE. Some minor changes in this ratio in NL were not consistent with the changes in PC or PE. In NL, the ratio of 16:1n-7/16:0 was higher in June (0.38) compared with the other samples for seasonal variation (0.15–0.25), and also 16:4n-3 was highest in June.

Dimethylacetals (DMA) from PE plasmalogens in the GC analyses were not identified. However, possible candidates with retention times slightly shorter than 18:0 (pers. comm. Y. Marty), never exceeded 5% of total fatty acids. Analysis of selected PE methyl ester fractions from the present study by Y. Marty (University of Brest, France) showed similar low content of DMA. Discrepancy with Soudant et al. (1995) and later works reporting higher levels of DMA may be attributed to incomplete derivation of alkenyl chains into DMA or differences between the populations.

DISCUSSION

Small changes were seen in the relative amounts of lipid classes and their respective fatty acid composition during development from recovering (3) to half-full (5) ovaries. This is consistent with the cellular changes during ovary development in *P. maximus*. In developing ovaries there is a discontinuous but ongoing recruitment of new cohorts of oocytes. A gradual accumulation of ripe oocytes is seen, with multiple cohorts of different development stages present at the same time (Paulet & Boucher 1991). Hence, changes in composition during ovary development have limited relation to individual oocyte development, particularly during the earliest stages. In empty ovaries (stage 2), the connective tissue may have a substantial contribution to the lipid content relative to

the young oocytes. Recovering (3) ovaries may have different cellular composition according to their history (Duinker & Nylund 2002). The recovering ovaries in the present study, more correctly termed as "almost spent", contained relatively few young oocytes in a mixture with developing and fully-grown oocytes (Duinker unpublished data). "Truly" recovering ovaries with numerous early vitellogenic oocytes in active development would better represent early oocyte development, but such ovaries were not found among the samples from September and October. The further stages of ovary development from filling (4) to half-full (5) also contain mixtures of several cohorts developing at the same time, but with increased accumulation of ripe oocytes. Hence, the changes in lipid composition during this development reflect a gradual increase in the proportion of ripe oocytes. If oocyte development had been a primary interest of the study, a size grading of oocytes after separation from the connective tissue would be a better approach. However, in this study the ovary development itself is of primary interest in comparison with seasonal changes.

During development from recovering (3) to half full (5) ovaries, both relative lipid composition and the total content per ovary increased concomitant with a corresponding increase in all lipid classes during the 10-fold increase in total lipid content. Triacylglycerols (TAG) was the dominant lipid class and increased from about 32% to 47% of total lipids between recovering (3) and half-full (5) ovaries. The levels are comparable with other studies of scallops (Napolitano & Ackman 1992, Soudant et al. 1996c, Pazos et al. 1997). Increase in neutral lipids (NL) is found both during conditioning (Soudant et al. 1996a) and with maximum maturity in other field studies (Besnard et al. 1989, Napolitano & Ackman 1992, Pazos et al. 1997). This probably reflects the increased relative incorporation of NL in the later phases of oocyte development. NL are generally used as energy reserve in all life forms (Sargent 1976), and Gallagher et al. (1986) found a strong decline in NL during embryogenesis prior to the onset of feeding in the larvae of *Crassostrea virginica*, *Ostrea edulis*, and *Mercuria mercenaria*. However, also phospholipids (PL) were utilized in the latter study with some difference among the bivalve species, and Delaunay et al. (1992) suggested an energetic role of PL in

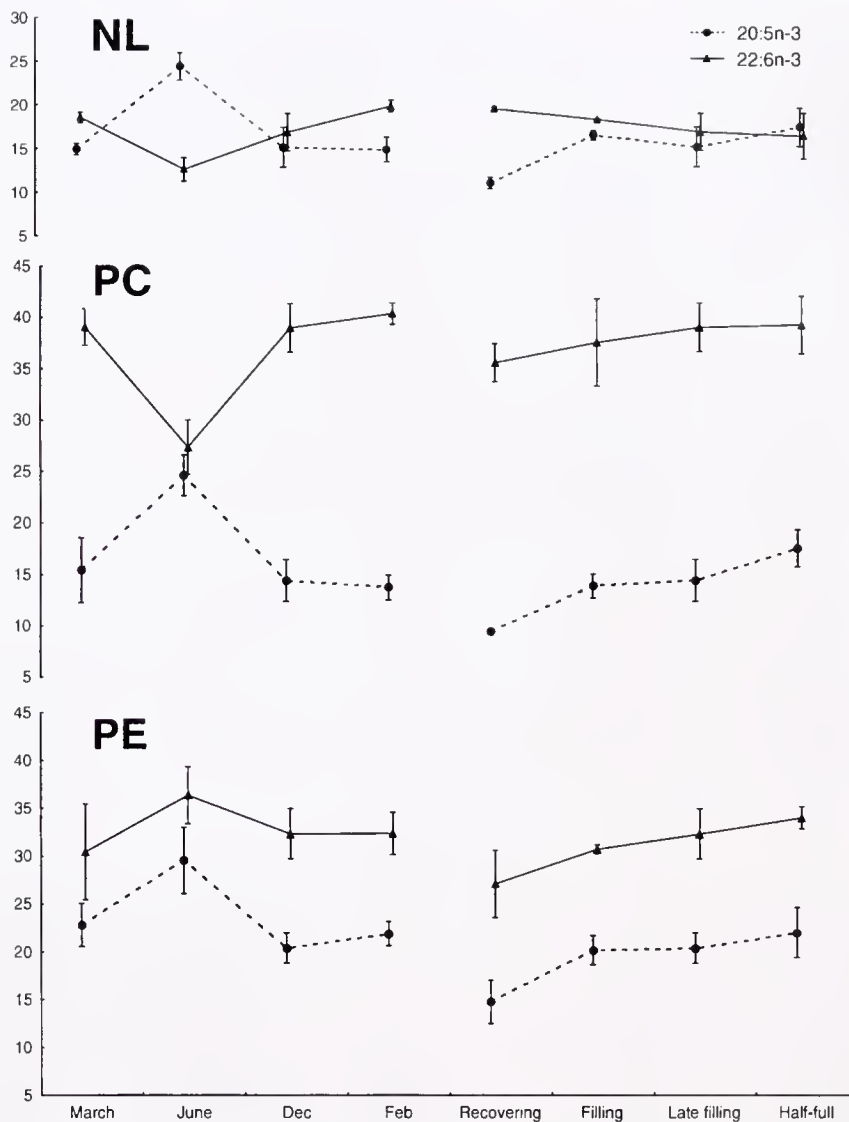

Figure 4. Relative content of 20:5n-3 and 22:6n-3 in the major lipid classes, neutral lipids (NL), phosphatidylethanolamine (PE) and phosphatidylcholine (PC). Vertical bars indicate standard deviations, $n = 3$. Recovering, filling, late filling and half-full ovaries were sampled on September 15, October 18, December 12, 1997 and February 7, 1998 respectively.

P. maximus larvae. Within the PL, the small changes in relative amounts of the different classes during ovary development largely agree with Soudant et al. (1996c). However, these authors found an increase in PC from 29% to 43% on the expense of plasmalogens during conditioning of *P. maximus*, mainly from start to first sampling after 5 weeks of conditioning. These gonads had been emptied by induced spawning at start of the experiment, however, and were hence in an earlier stage at the start of the experiment than the recovering ovaries in the present study. Also in the fatty acid composition small changes were seen during ovary development, in agreement with Soudant et al. (1996c).

The changes in fatty acid composition during ovary development were minor, however, compared with the differences seen in the samples for seasonal variation. The samples from June differed from the samples in February, March, and December, with a marked increase in 20:5n-3 on the expense of 22:6n-3 in PC and NL. One of the major events between March and June was the spring bloom, followed by the spring increase in temperature about

a month later (Strohmeier et al. 2000). The spring bloom in the study area is dominated by the diatom *Skeletonema costatum*, whereas different dinoflagellates and coccolithophorids dominate the rest of the year with only short incidents of diatom blooms (Erga & Heimdal 1984, B.R. Heimdal and A.B. Reisegg pers. comm. 1996). From analyses of algae cultures it is seen that diatoms tend to be rich in 20:5n-3 and relatively deficient in 22:6n-3, whereas various flagellates tend to be rich in 22:6n-3 and relatively deficient in 20:5n-3 (Ackman & Tocher 1968, Chuecas & Riley 1969, Volkman et al. 1981, Ackman 1983, Servel et al. 1994, Dunstan et al. 1994, Berge et al. 1995, Bell & Pond 1996, Soudant et al. 1996a). Large differences are seen among species, but the generalization is supported by analyses of plankton communities and in imprints in herbivores. With changes in dominance of diatoms and flagellates, Budge et al. (2001) found highest levels of 22:6n-3 in seston associated with flagellate dominance, and imprints of the two different types of phytoplankton communities have been reported in zooplankton (Pedersen et al. 1999, Shirai et

NL, neutral lipids; PE, phosphatidyletanolamine; and PC, phosphatidylcholine. * indicate significant differences between the recovering (3) and half-full (5) stages (Mann-Whitney U-test) sampled 15 September 1997 and 7 February 1998, respectively. Values are given as mean and standard deviation, n = 3.

al. 2002). It is hence likely that the spring bloom in March to April in the present study represented a major input of 20:5n-3 in the scallops with a lack of 22:6n-3, compared with the rest of the year with more abundance of 22:6n-3 in the phytoplankton. The change was probably facilitated by an exchange of gonadal material between March and June, as partial spawnings during spring and early summer were followed by gonad growth (Strohmeier et al. 2000). The major increase in the 20:5n-3/22:6n-3 ratio in the samples from June can hence be attributed to a diet effect. Influence of diatoms in the June samples is supported by the observation of increased ratio of 16:1n-7/16:0 and higher proportion of 16:4n-3, known as indicators of diatoms (Ackman & Tocher 1968, Chuecas & Riley 1969, Napolitano & Ackman 1992), in NL. The ratio and level are not as high, though, as diatom imprints reported by Pedersen et al. (1999) and Napolitano et al. (1997). Similar

changes are reported in other pectinids, with strong increase of 20:5n-3 in various tissues during diatom dominated spring blooms (Pollero et al. 1979, Napolitano et al. 1997). Pollero et al. (1979) found a marked increase in 22:6n-3, particularly in the gonads, associated with the dominance of a dinoflagellate in the stomachs of *Chlamys tehuella*. The importance of diet for the lipid composition of ovaries has also been emphasized in several studies of hatchery conditioning of bivalves (Helm et al. 1991, Utting & Doyou 1992, Soudant et al. 1996a, Soudant et al. 1996b, Soudant et al. 1996c, Soudant et al. 1999).

Changes in the composition of phospholipids due to different temperatures could be expected in the present study, according to mechanisms of temperature adaptation of membrane lipids to maintain a constant or optimal fluidity of the membranes (Williams & Hazel 1994). The temperatures of 8°C to 10°C prior to the

sampling in June and the 8°C to 9°C in December were higher than the winter minima for the March 1997 and February 1998 samples of 5°C to 6°C (Strohmeier et al. 2000). Different strategies for temperature adaptation are described, but usually the degree of unsaturation increases with lower temperatures (Williams & Hazel 1994), which is also seen in bivalves (Ueda 1974, Piretti et al. 1988, Chu & Greaves 1991). In *Placopecten magellanicus*, higher levels of 22:6n-3 in the phospholipids were found in the gonads at lower temperatures and higher depths, whereas higher content of a phytosterol was found in the adductor muscles (Napolitano et al. 1992). These sterols were not measured in the present study. The increased ratio of 20:5n-3/22:6n-3 in PC in June did not give a particular decrease in the degree of unsaturation itself. The fact that the same changes were seen in neutral lipids suggests that these changes were caused mainly by a diet effect as discussed earlier. However, the tendencies to elevated ratio of polyunsaturated to saturated fatty acids in PC in the colder months, relative to both the June and the December samples, may be related to temperature adaptation. This event was probably separate from the shifts in 20:5n-3 and 22:6n-3. In PE, there was an increase in the degree of unsaturation due to the coinciding increases in 20:5n-3 and 22:6n-3 in June (i.e., opposite to a possible effect on unsaturation due to temperature). It seems that the 22:6n-3/20:5n-3 ratio is more regulated in PE compared with PC.

Soudant et al. (1996a, 1996b) reported increased larvae survival under hatchery conditions associated with higher concentrations of 22:6n-3 and a higher 22:6n-3/20:5n-3 ratio in ovary and

egg phospholipids, and similar conditions give better growth in oyster larvae (Thompson & Harrison 1992). Soudant et al. (1996b) further suggested that a 22:6n-3/20:5n-3 ratio in diet greater than 1 was required to avoid deficiency, whereas a ratio greater than 2 is recommended for marine fish (Sargent 1995). Soudant et al. (1996b) also discussed the possibility that elevated levels of 20:5n-3 can have a negative effect on eicosanoid production from 20:4n-6 as seen in fishes (Bell et al. 1994). The differences in 22:6n-3/20:5n-3 ratio that gave impact on egg quality in the study of Soudant et al. (1996c) ranged between 5 and 1 in PC, which was more than the corresponding range from 2.7 to 1 in the present study. The order of magnitude of the changes in the present study may hence not be large enough to affect egg quality. However, the changes probably represent an annual change in the lipid composition status of broodstock from the field. Andersen and Ringvold (2000) found seasonal differences in effect of different broodstock diets on spawning success. This may be related to similar changes in lipid composition status as seen in the present study.

ACKNOWLEDGMENT

The authors thank Kjersti Ask and Thu Thao Nguyen for training and valuable help in the laboratory. The authors also thank Yanic Marty for inspiring methodological discussions. This work was supported by the Norwegian Research Council, project 111388/100 and National Institute of Nutrition and Seafood Research.

REPRODUCTIVE CYCLE OF COEXISTING MUSSELS, *MYTILUS CALIFORNIANUS* AND *MYTILUS GALLOPROVINCIALIS*, IN BAJA CALIFORNIA, NEW MEXICO

SERGIO CUIEL-RAMÍREZ AND JORGE CÁCERES-MARTÍNEZ*

Centro de Investigación Científica y de Educación Superior de Ensenada, Laboratorio de Biología y Patología de Organismos Acuáticos del Departamento de Acuicultura, Apdo. Postal 2732, 22800, Ensenada, Baja California, México

ABSTRACT The bay mussel, *Mytilus galloprovincialis*, and the California mussel, *Mytilus californianus*, are sympatric species in the Pacific coast of Baja California in northwest Mexico. To determine the reproductive cycle of both species in a coexistence area, a study of quantitative stereology was carried out from January to December 1995. *M. californianus* and *M. galloprovincialis* adults were collected from Mina del Fraile an exposed rocky shore and *M. galloprovincialis* adults were collected in a culture area a protected bay. In both species spawning organisms were found all year round. At population level, *M. galloprovincialis* had one major reproductive season from autumn to early spring in both sites. In late autumn, gonad follicles were full of ripe gametes and developing gametes and some spawning could occur. However, the spawning peak occurred in early winter. Minor spawning conditions were more frequent in *M. galloprovincialis* from the culture area than in *M. galloprovincialis* from the Mina del Fraile. These differences were presumably associated with the most stable environmental conditions in the culture area, which could also influence differences in percentage of storage cells found from spring to summer. The reproductive season of *M. californianus* took place from winter to summer. The major reproductive activity occurred in spring and the resting season took place during autumn. The reproductive season of *M. californianus* in the studied locality is from winter to summer, whereas the reproductive season of *M. galloprovincialis* occurs from autumn to early spring.

KEY WORDS: coexistence, reproductive cycle, spawning, *Mytilus galloprovincialis*, *Mytilus californianus*

INTRODUCTION

The mytilids, *Mytilus californianus* (California mussel) and *Mytilus galloprovincialis* (bay mussel), coexist in the southern part of the west coast of North America. The distribution of *M. californianus* is from Alaska to Islas Socorro in Mexico, and the distribution of *M. galloprovincialis* is from central California to Baja California, Mexico (Soot-Ryen 1955, Mc Donald & Koehn 1988, Koehn 1991, Seed 1992, Suchanek et al. 1997). The genetic divergence between *M. californianus* and *M. galloprovincialis* and their external morphology have been clearly differentiated and, in spite of the fact that they are sympatric species, there is no hybridization between them (Martínez-Lage et al. 1997, Martínez-Lage et al. 2002, Cáceres-Martínez et al. 2003, del Río-Portilla & Cáceres-Martínez, in prep.). Studies on the reproductive cycle of coexisting species aid in explaining their coexistence strategy. Suchanek (1981) from field studies carried out in Alaska and Washington stated that the reproductive strategy of *Mytilus californianus* is based on continuous spawning at a very low level throughout an annual cycle. *Mytilus edulis* (knowing now that bay mussels in Alaska and Washington correspond to *M. trossulus*) is a classic fugitive species that rarely reaches a large size, but matures early and is characterized by a single massive reproductive output each year.

Different techniques have been used to assess the reproductive condition in mussels. A summary on studies of reproduction seasons in mussels from North America is shown in Figures 1 and 2. Seed (1976) from an analysis of reproduction records for several mytilids from various parts of their geographical range noted that mussels from the warmer more southerly waters of the Northern Hemisphere generally spawn earlier than those further north. Southern species usually reproduce later in the year and have a progressively restricted season further north; northern species ex-

hibit the reverse trend, spawning earlier and with a more extended season further south. A wide reproductive period in the southern part of the Northern Hemisphere has also been observed in other studies (Ferrán 1991, Villalba 1995, Cáceres-Martínez & Figueras 1998).

Minor local variations in the reproductive cycle of the same mussels species has also been studied. Seed (1976) described that the gonadal development of *Mytilus edulis* in England was faster in mussels from the low intertidal zone, than in those from the upper zone and he related these results to food availability. Local variations in the gonadal cycle of *Mytilus galloprovincialis* were found in Spain and these differences were associated with environmental conditions (Ferrán 1991, Villalba 1995), but the gonadal cycle of wild *M. galloprovincialis* from the low intertidal exposed rocky shores and from those cultured in floating rafts was similar (Cáceres-Martínez & Figueras 1998).

There are no studies on the reproductive cycle in coexisting *M. galloprovincialis* and *M. californianus* from the same exposed rocky shore in Baja California, Mexico (the southern distribution area of *M. galloprovincialis* and *M. californianus* in the Pacific coast of North America) or on the comparison of the reproductive cycle between *M. galloprovincialis* from exposed and culture conditions. The objectives of this study are to determine the time and duration of the reproductive period of *M. californianus* from exposed conditions, and of *M. galloprovincialis* from exposed and culture conditions through quantitative stereology.

MATERIALS AND METHODS

To determine the reproductive cycle using the proportion of germinal and storage cells in the natural population and the cultured *Mytilus galloprovincialis* and the natural population of *Mytilus californianus*, two samplings were planned from January to December 1995. The first sampling was carried out in an exposed rocky shore named Mina del Fraile south of Bahía de Todos Santos (Fig. 3) where *M. galloprovincialis* and *M. californianus* coexist in

*Corresponding author. E-mail: jcaceres@cicese.mx

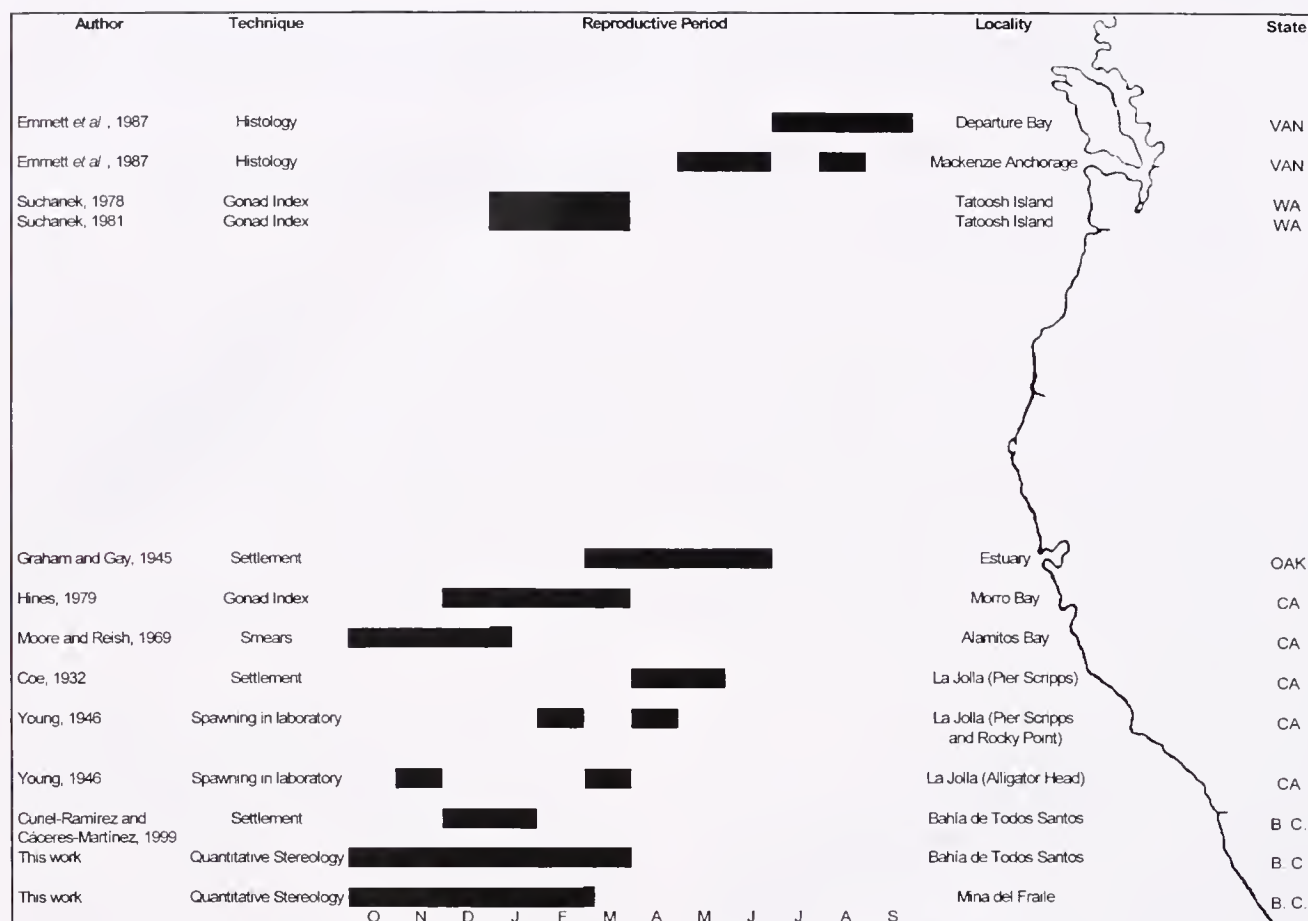

Figure 1. Reproductive cycle of bay mussels along the west coast of North America. All records of *Mytilus edulis*-like from Alaska to northern California were considered as *M. trossulus*, bay mussels from northern California were considered as possible hybrids between *M. trossulus* and *M. galloprovincialis*, while bay mussels from central California to Baja California, México, were considered as *M. galloprovincialis* (Soot Ryen 1955, McDonald & Koehn 1988, Koehn 1991, Seed 1992, Suchanek et al. 1997). The Figure is arranged from north to south.

the intertidal zone. Each month, 30 individual adults from each species were recollected from the middle intertidal zone during low tide periods. The morphologic differentiation of both species at the adult stage was easy. See the morphologic criteria established by Cáceres-Martínez et al. (2003). A total of 360 mussels from each species were sampled; their mean shell length was 57 ± 5.8 mm for *M. californianus*, and 63 ± 8.2 mm for *M. galloprovincialis*. The second sampling was carried out taking 30 *M. galloprovincialis* adults from culture ropes (5 m depth) each month in the culture area located in Bahía de Todos Santos (see Fig. 3). A total of 360 mussels with a mean shell length of 64 ± 6.3 mm were sampled. Mussels from both samplings were brought to the laboratory in plastic bags and were cleaned with a brush and a jet of seawater.

The soft tissue from each mussel was fixed in Davidson's fixative (Shaw & Batle 1957). An anterior transverse section was taken, including the mantle tissue. Histologic sections with a thickness of 5 μ m were cut and stained with hematoxylin and eosin. The presence of gametes and storage cells were determined by quantitative stereology using a Weibel (1969) graticule following the method described by Briarty (1975), Lowe et al. (1982), Seed and Suchanek (1992), and Cáceres-Martínez and Figueras (1998). Five random counts were carried out on each histologic slide. Results are given as a percentage of mantle volume occupied by

the gamete development stages and cell types or mantle components (MC) defined as ripe gametes (RG). In the female, it is the stage in which oocytes were free within the follicles and some oocytes remained attached to the follicle wall; whereas in the male, it is the stage when follicles were filled by spermatozoa arranged in characteristic bands. Similar to the females during the developing stage of gametes (DG) when rounded oocytes along with oocytes were found attached to the follicle wall, in the male varying quantities of developing spermatogenic cells were present. Additional observations on the presence of hemocytes around gametes, and conditions of the follicle walls were recorded to determine if gamete reabsorption was occurring. The other cell components in the gonad were vesicular cells of connective tissue (VCT) and adipogranular cells (AC); empty follicles (EF) were recorded when the points of the graticule indicate an empty area inside the follicle.

The one-way ANOVA was used to determine if gametes (RG and DG) were different among mussel species throughout the study period in both localities and species (Sokal & Rohlf 1987).

RESULTS

Variations in percentage of the different cell types in the mantle volume of *Mytilus galloprovincialis* from the culture area are shown in Figure 4A. RG and DG were found throughout the study

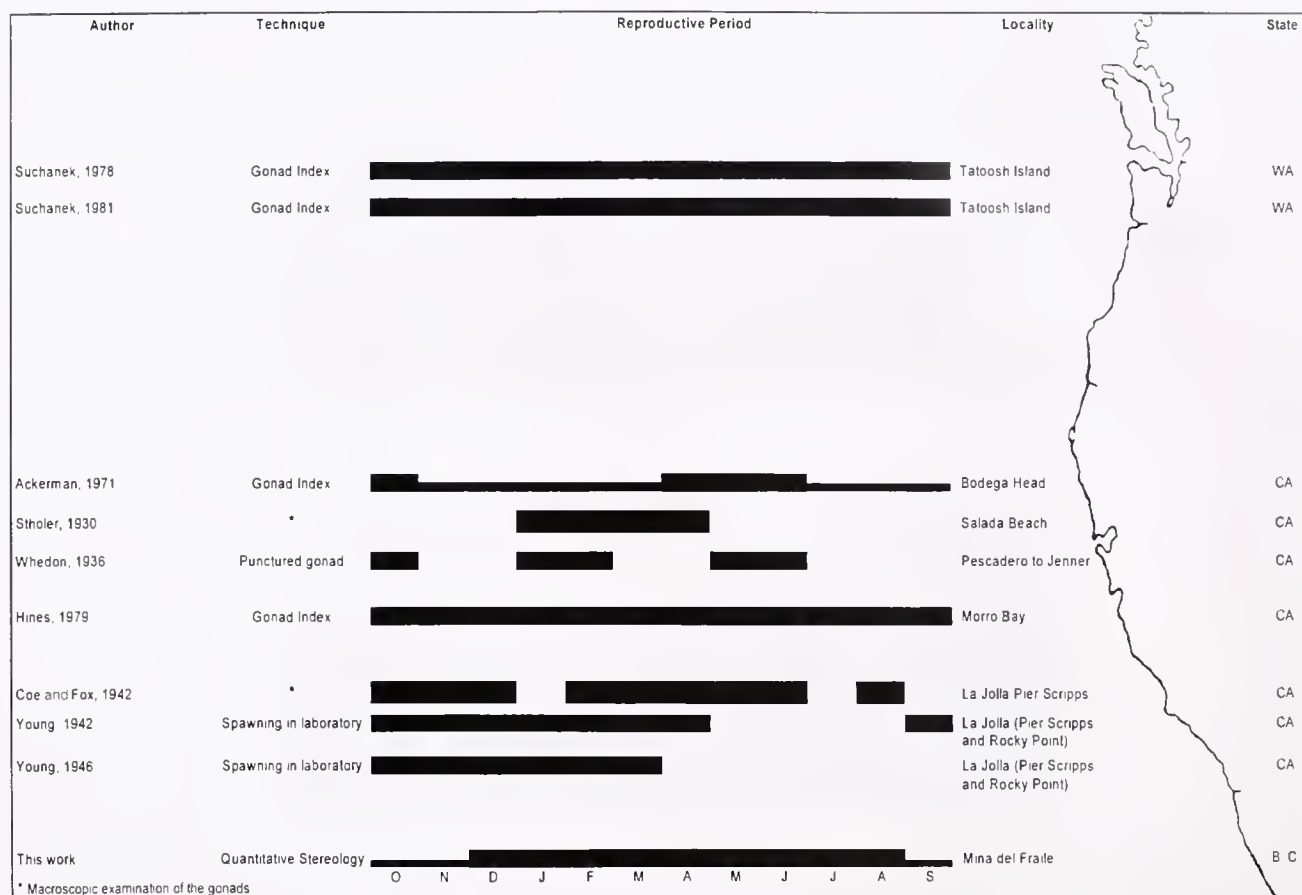

Figure 2. Reproductive cycle of the California mussel *Mytilus californianus* along the west coast of North America. The Figure is arranged from north to south.

period. RG and DG reached their maximum levels in October and November indicating a major spawning period, but remained up to 50% from December to April. EF were from 12.9% in October to 24.2% in March, values of RG and DG in April were around 50%, but gametes were surrounded by hemocytes and follicle walls were in regression, showing a reabsorption period. The reproductive season started in October and ended in March. AC reached their maximum from May to September whereas VCT rose from April to September showing the storage of reserves during spring and summer, which would be used for the next massive gametogenesis. Variations in percentage of the different cell types in the mantle volume of this species from the exposed rocky shore are shown in Figure 4B. RG and DG were also found throughout the study period with their maximum values in November showing a major spawning period, their prevalence remained up to 40% from December to March, when reabsorbing conditions were observed, reaching minimum values from June to September. EF were recorded throughout the study period reaching their higher values from 18.5% in November to 26.6% in February. At this time, AC were in a lower proportion with minimum values in January and February. VCT were present throughout the study period with maximum values from June to September. The percentage of MC was similar to those described above for this species in culture conditions from November to February; and it was different from March to September, the period when the accumulation of reserves was more intense. In general, differences in percentage of gametes

throughout the study period in both localities were significant ($F_{(2, 4907)} = 301, P = < 0.01$).

The variations in percentage of the different cell types in the mantle volume of *Mytilus californianus* from the exposed rocky shore are shown in Figure 4C. RG and DG were found throughout the study period with minimum values from August to December, while maximum values were recorded from January to July (up to 40%). Their maximum values were reached from February to June showing the major spawning activity. EF were recorded throughout the study period at similar percentage values. AC were recorded in all the months sampled, with maximum values in September and October (storage of reserves); their minimum values were reached from March to May. VCT were present throughout the study period with maximum values from September to December. Differences in percentage of gametes throughout the study period in both localities and species were significant ($F_{(2, 4907)} = 301, P = < 0.01$).

DISCUSSION

The reproductive season of *Mytilus galloprovincialis* cultured in Bahía de Todos Santos is more extended than those from the same species in the exposed rocky shore from Mina del Fraile. These observations could be related to environmental conditions. Culture mussels feed underwater at all times and they are not exposed to environmental changes such as desiccation or to sharp

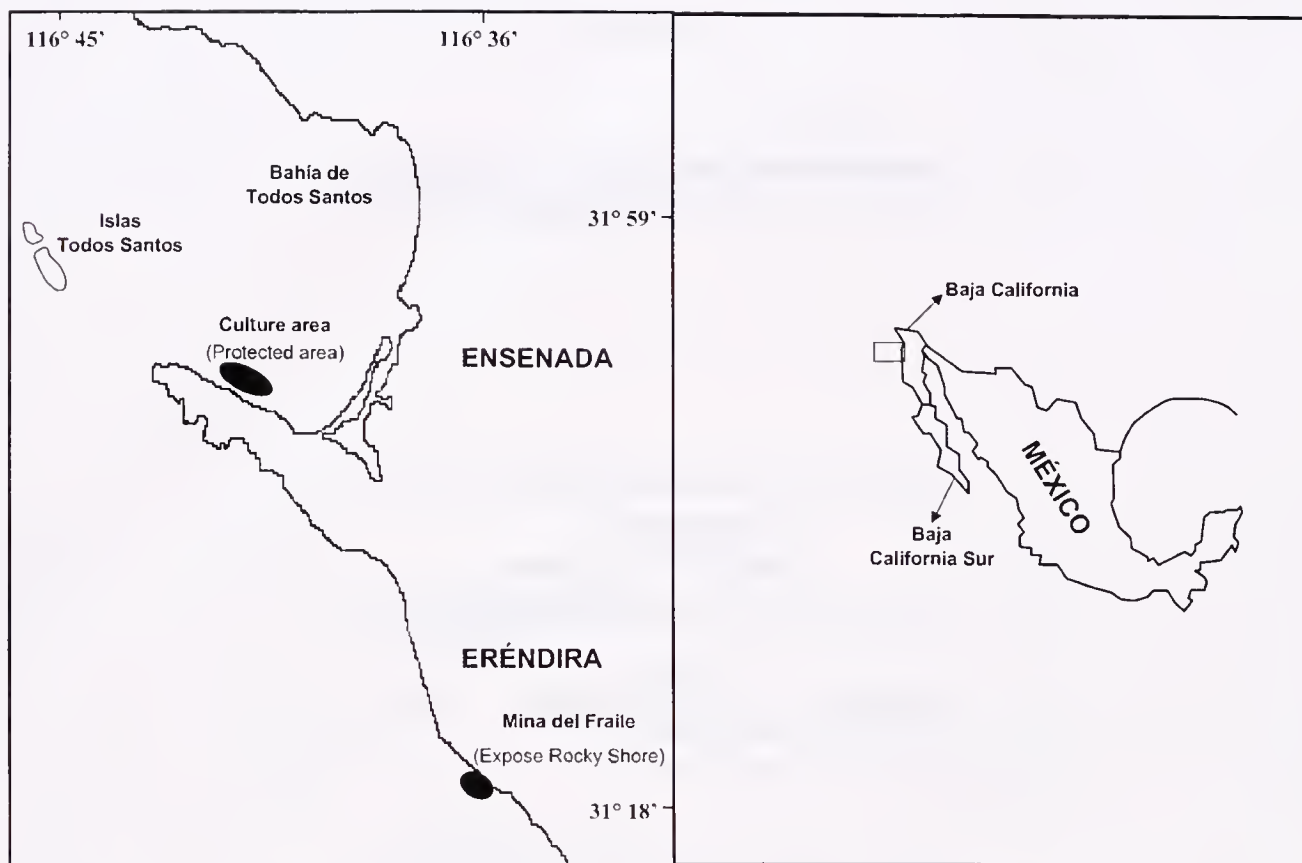

Figure 3. Map showing the mussel culture area in Bahía de Todos Santos and the exposed rocky shore in la Mina del Fraile, Baja California; where *Mytilus galloprovincialis* and *Mytilus californianus* were collected for the study.

temperature changes due to tides at midnight or midday. Thus, external conditions during the season of reserves accumulation (i.e. temperature changes, food availability, wave splash, and photoperiod) seem to be more stable in the culture condition than in exposed rocky shore conditions, allowing a more frequent and intense reproduction (see Fig. 4, A,B). Seed (1976) described that the gonadal development was faster in mussels from the low intertidal than in those from the upper intertidal, relating these results to food availability. Ferrán (1991) and Villalba (1995) associated local variations in the gonadal cycle of mussels cultured in Galician bays in Spain to environmental conditions.

Comparing the reproductive season of *M. galloprovincialis* with *M. californianus* it is observed that in some months the percentage of MC was similar in culture or exposed rocky shore conditions; however, the reserves accumulation period between species shows differences in reproductive cycles. The most intense spawning period in *M. californianus* occurred from middle winter to spring. It is clear that *M. californianus* presents a more extended reproductive season from winter to summer, suggesting that endogenous factors, regulating the reproductive cycle in this species, and the exogenous factors act in conjunction in different ways in comparison to *M. galloprovincialis*.

A comparison of the reproductive season of *M. galloprovincialis* found in this study at regional scale showed a similar pattern to those described for the bay mussel from Washington to southern California (see Fig. 1), which shows a reproductive season between October and April, with the exception of the studies by Graham and Gay (1945), Coe (1932) and Young (1946) in the Pier of Scripps Institution of Oceanography and Rocky Point. The first

two authors arrived to the conclusion that through spatfall studies; thus it is probable that spawning period could be earlier than stipulated. The last author came to his conclusion from spawning induction in laboratory, which does not represent the reproductive conditions of the mussel population in the wild. There seems to be a pattern of reproduction period from autumn to early spring of bay mussels from Washington to Baja California and from spring to summer in Vancouver Island. Are these differences related to the bay mussel species *Mytilus trossulus* towards north, and *Mytilus galloprovincialis* towards south? Or to latitudinal and local conditions? A comparison on reproductive seasons of the bay mussels (*M. trossulus* and *M. galloprovincialis*) is necessary using the same technique in the north western coast of North America to determine the reproductive strategy of these two bay mussel species.

On the other hand, reproductive periods of *Mytilus californianus* recorded in the Pacific coast of North America (see Fig. 2) show spawning periods almost all year round. Our results and those from the mentioned studies in Figure 2, support in part the observations by Suchanek (1981) mentioning that the reproductive strategy of *M. californianus* is based on continuous spawning at very low level throughout an annual cycle. However, more studies on the spawning intensity or level of this species all year round in comparison to *M. galloprovincialis* are needed to confirm the observation by Suchanek.

The results of this study show that *M. galloprovincialis* has a less extended reproductive season in the rocky shore exposed environment than in the culture conditions, and the reproductive cycle of this species in both localities is less extended than those

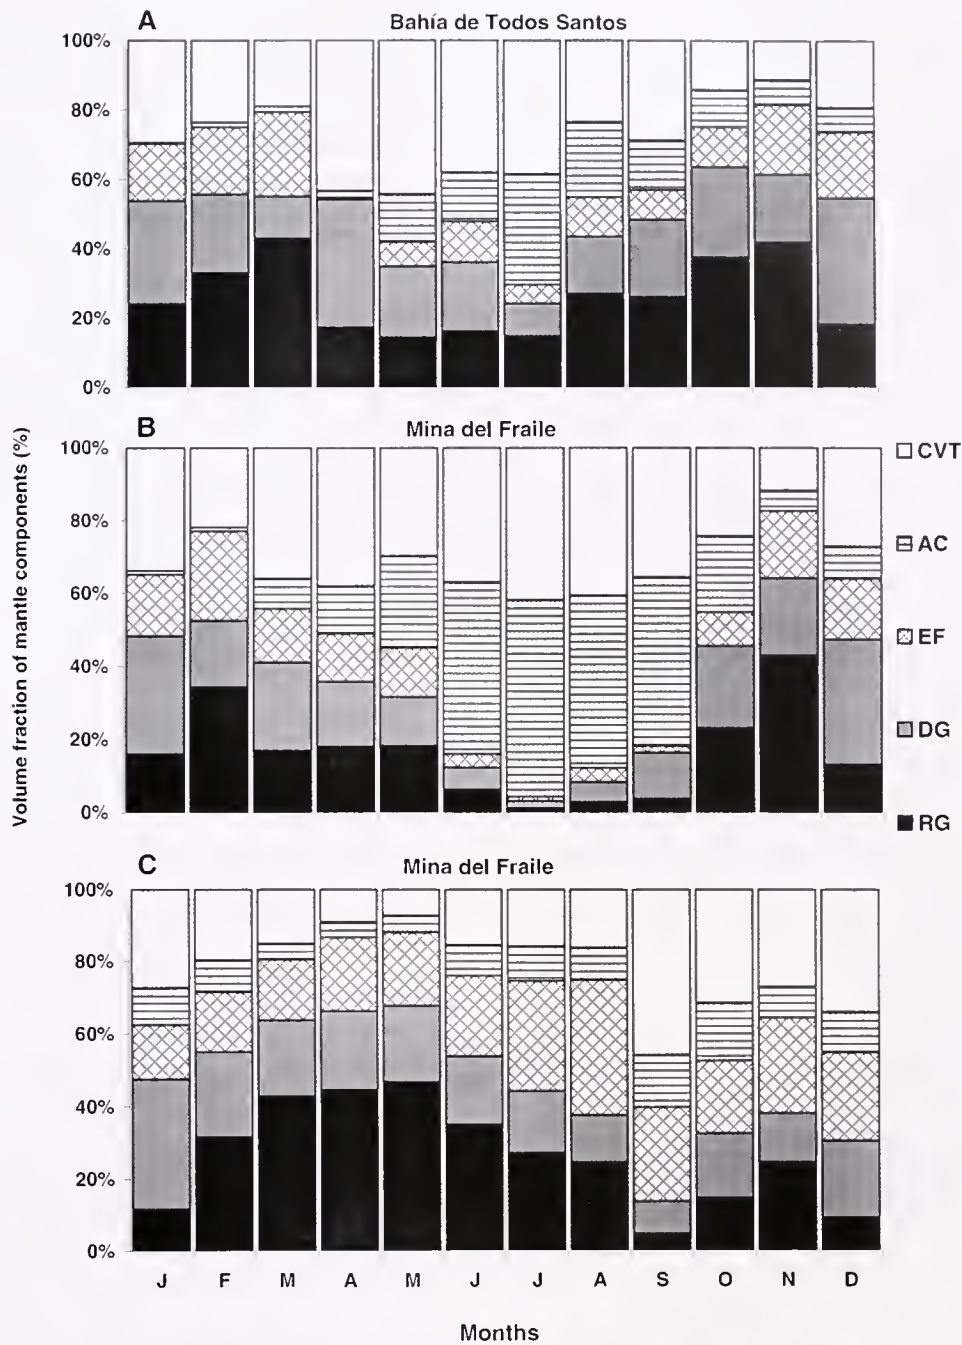

Figure 4. Variations of the volume percentage of mantle components of *Mytilus galloprovincialis* from the culture area (A), *Mytilus galloprovincialis* from the exposed rocky shore (B), and *Mytilus californianus* from the exposed rocky shore (C), during the study period. Ripe gametes (RG), Developing gametes (DG), empty follicles (EF), adipogranular cells (AC) and vesicular cells of connective tissue (VCT).

of *M. californianus* in the exposed rocky shore environment. This period takes place from autumn to early spring, whereas for *M. californianus* it takes place from winter to summer, both species having smaller spawning periods all year long.

The mussel settlement season in Bahía de Todos Santos has been recorded in December and January (Curiel-Ramírez & Cáceres-Martínez 1999, Curiel-Ramírez 2000), coinciding with the spawning observed for *M. galloprovincialis* in this study. Current studies on the identification of recently settled mussels supports the fact that the majority of the spat from these months correspond to this species (Curiel-Ramírez & Cáceres-Martínez, in

prep), such as it had been mentioned about the necessity of studies on the intensity of spawning in these species. Also, studies are necessary on the settlement intensity of both species by identification of recently settled mussels during the year.

TEMPORAL VARIATION IN THE SETTLEMENT OF BLUE MUSSELS (*MYTILUS EDULIS* C. LINNAEUS, 1758 AND *M. TROSSULUS* GOULD 1850) IN EASTERN MAINE

PAUL D. RAWSON,* AFTON MCGOWEN, AND CHRIS BARTLETT

School of Marine Sciences University of Maine, Orono, Maine, 04469 and Maine Sea Grant Program Eastport, Maine 04631

ABSTRACT Blue mussels in the genus *Mytilus* are cultured extensively in the Northeastern United States and throughout much of Atlantic Canada. Recent reports suggest that of the two species that co-occur in this region, the economic value of *Mytilus edulis* is higher than that of its congener *M. trossulus*. Because mussel farmers typically rely on wild caught spat to seed grow-out facilities, the productivity of mussel farms may benefit from a method of spat collection that limits the frequency of *M. trossulus* spat. To explore the potential for developing such a method in eastern Maine, where *M. trossulus* is highly abundant, we investigated the spatial and temporal variation in the proportion of *M. edulis* and *M. trossulus* spat settling at three sites in Cobscook Bay, Maine, USA in 2000. We found little evidence of location- or depth-dependent variation in the frequency of *M. edulis* spat. There was a significantly greater proportion of *M. edulis* spat on the collectors retrieved in October and December relative to those retrieved in August and September. However, the low abundance of settlers in October and December, coupled with the likelihood that spat settling late in the year will experience low growth rates and high mortality as a function of rapidly declining water temperature and food supplies, suggests that there are significant impediments to the preferential collection of *M. edulis* seed within Cobscook Bay.

KEY WORDS: settlement, spat collection, mussel culture, spatial variation, temporal variation, *Mytilus*

INTRODUCTION

The blue mussel, *Mytilus edulis* (C. Linnaeus 1758), is a common, rocky intertidal and subtidal bivalve mollusk, which is harvested extensively in the Northeastern United States and Atlantic provinces of Canada. Despite a growing market demand for blue mussels in the U.S., the domestic production of mussels has steadily declined from a peak of 4800 metric tons in 1988 to 1400 metric tons in 2001 (NMFS 2003). Among the states contributing to the U.S. production, the vast majority (~88%) are harvested in Maine. Historically mussels have been harvested from natural beds and bottom culture leases seeded with juvenile mussels. Recently, however, mussel culturists in Maine have adopted suspended raft techniques commonly used in parts of Europe and Atlantic Canada. Because off-bottom techniques use a much greater proportion of the water column they are much more efficient and produce a product considered to have superior meat yield and quality relative to that obtained from bottom culture (Lutz 1980, Hickman 1992, Roberts et al. 1999). Although the majority of suspended raft and other off-bottom culture operations are presently located on the central coast of Maine, potential suspended raft culture sites can be found throughout much of the state.

The presence of a second species of blue mussel, *M. trossulus* (Gould 1850), however, may present an impediment to the expansion of raft culture to sites in eastern Maine. Genetic surveys using allozyme electrophoresis and PCR-based molecular markers have shown that *M. trossulus* is widely distributed throughout the Canadian Maritime Provinces, often in mixed populations with *M. edulis* (e.g., Koehn et al. 1976, 1984, Bates & Innes 1995, Comesaña et al. 1999, Innes & Bates 1999, Mallet & Carver 1999, Penney & Hart 1999, Penney et al. 2002). Recently, Rawson et al. (2001) found that blue mussel populations throughout much of eastern Maine contain relatively high frequencies of *M. trossulus*, as well. Freeman et al. (1994) have shown that *M. trossulus* mus-

sels obtain less meat than *M. edulis* mussels and are more prone to shell fracture during processing. In addition, given species-specific growth rates, Mallet and Carver (1995) have estimated that the economic value of *M. edulis* is 1.7 times that of *M. trossulus* under off-bottom culture conditions. Because raft culture facilities are typically seeded with wild caught mussel spat, the proportion of *M. edulis* and *M. trossulus* under cultivation is dependent on the relative frequency with which these species settle on spat collectors. Thus, in locations where *M. edulis* and *M. trossulus* are sympatric, a method of spat collection that favors *M. edulis* seed and limits the frequency of *M. trossulus* seed would be highly beneficial to the productivity of suspended culture facilities (Freeman 1996).

The development of such methods, in turn, is dependent upon there being sufficient temporal or spatial variation in species-specific settlement. Freeman et al. (2002) and Kenchington et al. (2002) explored the potential for the differential settlement of *M. edulis* and *M. trossulus* larvae at depth in mesocosm and field studies, respectively. The results of their mesocosm study suggest that species-specific larval behaviors result in the greater settlement of *M. edulis* at depth when there is no thermocline present. In their field studies, they examined the patterns of mussel settlement at two sites in Nova Scotia, Canada, throughout the spawning season in 3 successive years. Although the timing of species-specific settlement varied among years, they consistently observed a significantly higher percentage of *M. edulis* spat on collectors deployed 4–5 m below the surface. Based on their results, they recommended that mussel growers consider deploying subsurface spat collectors to increase the proportion of *M. edulis* postlarvae.

In this study, we investigated the spatial and temporal variation in the frequency of *M. edulis* and *M. trossulus* settlement at three sites in Cobscook Bay, Maine, USA to determine whether such variation will facilitate the development of spat collection methods favoring *M. edulis* and the expansion of raft culture operations to eastern Maine. Although our sampling strategy differs somewhat from that of Kenchington et al. (2002), we were particularly interested in whether the increased settlement of *M. edulis* with depth observed by Kenchington et al. (2002) is found elsewhere in the zone of sympatry between *M. edulis* and *M. trossulus*.

MATERIALS AND METHODS

Spat Collection

The temporal and spatial patterns of mussel settlement were investigated by placing spat collectors at three locations in Cobscook Bay (Fig. 1). Cobscook Bay is an extremely dynamic embayment where the morphology of the bay in combination with a large tidal range (>8 m) creates strong directional flows within much of the bay (Brooks et al. 1999). We placed spat collectors at three sites that lie within the major flow patterns within the bay. All three sites were located 30–50 m from shore in approximately 35–40 m of water (at low tide). Collectors were suspended from the peripheral anchor lines and buoys of salmon net pens at Shackford Head (SH), from an equipment supply raft on a salmon aquaculture site in South Bay (SB), and from the anchor lines of an experimental scallop farm in East Bay (EB). Spat collectors consisted of 6 m lengths of aged and frayed 13-mm thick polypropylene rope, also known as “pot warp”. Each collector was suspended from the surface and weighted at the bottom using cinder blocks (12.3 kg) to keep the collector vertical in the water column. Three replicate collectors were initially deployed at each site on June 27, 2000 and recovered on August 8 at which time a second set of collectors was deployed. Collectors were recovered and redeployed on September 28 and October 28, and the experiment was terminated when the last set was retrieved on December 28. Upon recovery, the spat collectors were cut into three 1.5-m sections (top, middle, and bottom) starting from the surface. Each section was placed in an individual Ziploc bag containing 95% ethanol, and transported on ice to the University of Maine where they were stored at 4°C. Subsequently, each rope section was removed from the 95% ethanol, the rope strands were unwound, and all spat gently removed. These spat were combined with any

that had fallen off and settled to the bottom of the Ziploc bag, counted by hand, placed in 50-ml centrifuge tubes containing fresh 95% ethanol, and stored at 4°C.

Molecular Analysis

Previous studies investigating genetic variation in northwest Atlantic blue mussel populations have used various combinations of allozyme and PCR-based markers to identify *M. edulis* and *M. trossulus* individuals and their hybrids (e.g., Koehn et al. 1976, 1984, McDonald et al. 1991, Bates & Innes 1995, Comesaña et al. 1999). Because PCR-based methods require very little tissue they are ideally suited to studies involving larvae or recently settled postlarvae. Thus, we estimated the proportion of *M. edulis* and *M. trossulus* among the spat on each section of rope using two PCR-based genetic assays. Template DNA was prepared from approximately 20 individual spat from each rope section by placing whole spat in a 0.5-mL microcentrifuge tube containing 20 ng of proteinase K in 10 µL of a buffer containing 50 mM KCl, 10 mM Tris-HCl (pH 9.0), 0.1% Triton X-100 and incubating at 55°C for 3 h on a rotating platform. The samples were heated to 95°C for 15 min before 10 µL of GeneReleaser (BioVentures Corp.) was added. The resulting mixtures were incubated at 65°C for 30 s, 8°C for 30 s, 65°C for 90 s, 97°C for 180 s, 8°C for 60 s, 65°C for 180 s, 97°C for 60 s, and finally 65°C for 60 s, after which the samples were centrifuged at full speed (13,200 rpm) for 2 min. The supernatant containing DNA was transferred to a new 0.5-mL microcentrifuge tube and was stored at 4°C. The isolated DNA was used in the PCR-based Glu-5' and ITS genetic assays that are considered diagnostic for *M. edulis* and *M. trossulus*. The application of these markers followed the protocols described in Rawson et al. (1996) and Heath et al. (1995), respectively.

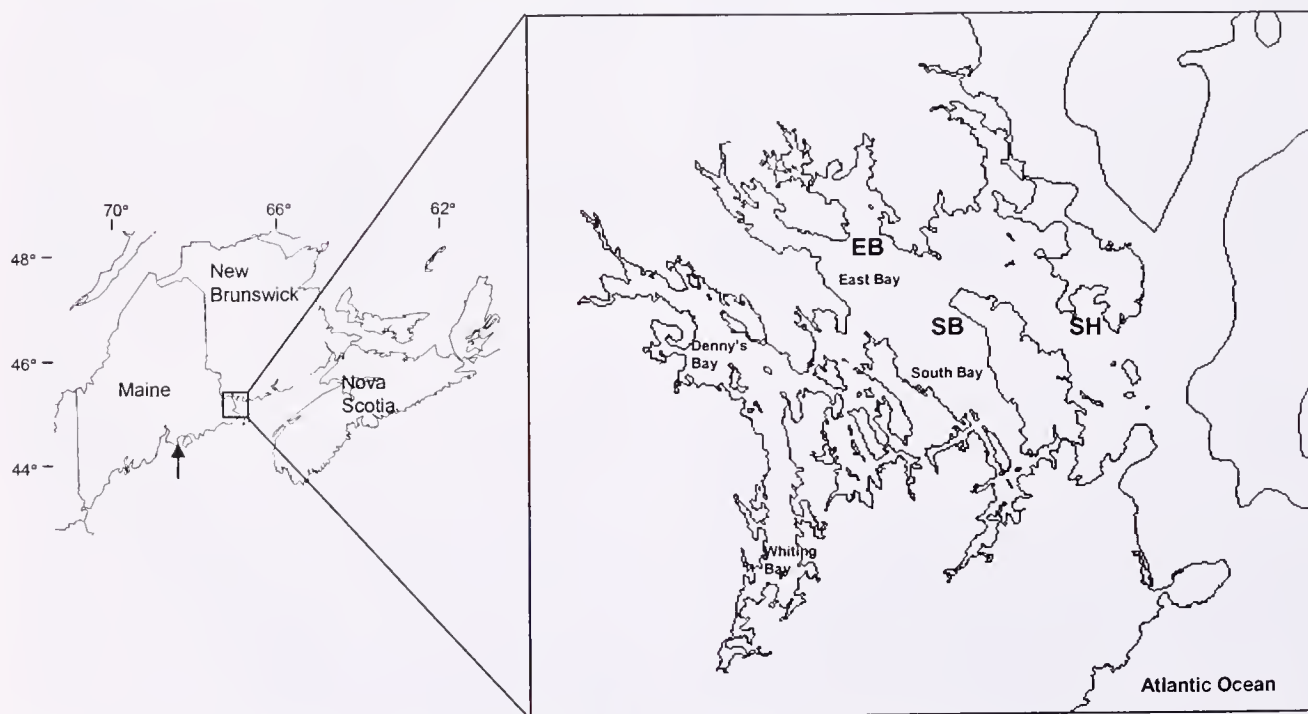

Figure 1. Locations in Cobscook Bay, Maine, USA where spat collectors were deployed. Site designations are given in the text. The arrow in the left panel indicates the approximate location of the Blue Hill Salt Pond where, at present, the majority of mussel seed are obtained by mussel growers in Maine.

Statistical Analysis

Variation in the combined settlement of *M. edulis* and *M. trossulus* with respect to site, date of collection, and depth was analyzed by a 3-way full factorial fixed effects (model I) analysis of variance (ANOVA). Of the 36 ropes deployed in this study, four were lost prior to recovery. Although no more than one rope was lost at any single location during any sampling period, this creates imbalance in our dataset so that the appropriate F statistics for the main effects and all interaction terms were estimated using Type III sums of squares. To eliminate heteroscedasticity among the residuals, total counts of spat abundance were log transformed prior to analysis. The validity of the model and data transformation was further determined by testing whether the residuals were normally distributed using a Levene's test.

Variation in the frequency of *M. edulis* Glu5' and ITS alleles among the spat recovered from individual rope segments was also analyzed using ANOVA. For many of the ropes retrieved in August, October, and December, we were unable to find and genetically characterize more than a couple (<5) spat per rope segment (Table 1). This created a severe imbalance in our dataset and precluded the use of a 3-way ANOVA to simultaneously analyze site- and depth-specific variation in the frequency of *M. edulis* alleles across all four sampling periods. Thus, to analyze temporal variation in the abundance of *M. edulis* spat, we first calculated the *M. edulis* Glu5' allele frequency among the spat collected and genotyped at each site within each month, without regard for individual ropes or depths. The site-specific allele frequencies were then analyzed in a 1-way ANOVA with sampling date as the independent variable. One of our main goals in this study is to investigate whether species-specific settlement varies as a function of depth. In this regard, we obtained sufficient allele frequency data to analyze the depth- and site-specific variation in the frequency of the *M. edulis* Glu5' allele for the ropes collected in September using a 2-way fixed effects ANOVA. In both analyses, the frequency of the *M. edulis* Glu5' allele was normalized using an arcsin-transformation. The appropriate F-statistics for the main effects and any interaction terms were constructed using Type III sums of squares and the validity of the model and data transformation determined by graphical analysis of the homogeneity of the residuals and testing whether the residuals were normally distributed using a Levene's test. An identical approach was also used to examine the degree to which variation in the frequency of the *M. edulis* ITS allele was related to location, depth, or sampling date.

RESULTS

We observed substantial spatial and temporal variation in the settlement of blue mussels, *M. edulis* and *M. trossulus*, in Cobs-

TABLE 1.

Number of rope segments (spat collectors) for which ≥ 10 spat were retrieved and genetically identified during the 4 sampling periods in this study. Three depths were sampled with T, M, and B corresponding to the top, middle, and bottom 1.5 m rope segments, respectively.

	August			September			October			December		
	T	M	B	T	M	B	T	M	B	T	M	B
Shackford Head	0	2	0	3	3	3	2	2	2	1	2	2
South Bay	0	0	0	3	2	3	1	1	1	0	2	1
East Bay	1	1	2	2	2	1	1	1	1	0	0	0

cook Bay. The total abundance of mussel spat on rope segments varied from 0 on collectors retrieved from East Bay in December to nearly 1,500 per 1.5 m rope segment at Shackford Head in September (Fig. 2). The 3-way ANOVA model explained over 90% of the variance in settlement in our data set (adjusted $R^2 = 0.90$; $F = 15.06$; $P < 0.001$) and identified a significant interaction involving all three of the main effects in the model (Table 2). This interaction is primarily due to a shift from a positive association between the abundance of settlers and depth in August and December to a negative association in September and October at Shackford Head, and only a weak dependence of spat abundance on depth at the other two sites (see Fig. 2). Two of the main effects in this model, month and site, were also significant. In general, blue mussel settlement was much higher at Shackford Head compared with both the East Bay and South Bay sites, up to 5-fold higher in the September and October collections. Peak settlement occurred in September at all three locations, whereas much lower settlement was observed on the collectors retrieved in October and December and virtually no spat were found on the collectors recovered in August.

We isolated DNA from a total of 1316 spat sampled from 48 rope segments and successfully genotyped 1249 (95%) of these individuals at the Glu5' marker. Our success rate for the ITS marker was lower and only 1022 spat were successfully genotyped at this marker. Of the 1020 individuals that successfully genotyped both markers, the allele frequency variation at the Glu5' marker was highly correlated with the variation at the ITS marker across sampling date, site, and depth ($r = 0.95$; $P < 0.001$). Because the statistical analyses of the variation at the Glu5' and ITS markers are quantitatively and qualitatively similar and the higher success rate for the Glu5' marker, we have chosen to present only the ANOVA results pertaining to the spatial and temporal variation in the frequency of the *M. edulis* Glu5' allele.

The frequency of the *M. edulis* Glu5' allele was fairly consistent within collection dates and across depths and the majority of the variation in *M. edulis* Glu5' allele frequency occurred between sampling dates (Fig. 3). Unfortunately, the lack of settlers on many of our collectors precluded a formal statistical analysis of allele frequency variation with respect to depth at all three sites across all four collection dates. However, we pooled the frequency data across sites and depths and used a 1-way ANOVA to investigate whether there was significant temporal variation in the frequency of the *M. edulis* Glu5' allele. This model was highly significant (adjusted $R^2 = 0.95$; $F = 41.00$; $P < 0.001$; Table 3) and *post hoc* tests, (Tukey's) of means indicated that significant differences in the average allele frequency of the *M. edulis* Glu5' allele occurred between sampling dates. This significant difference is due to an increase in the frequency of the *M. edulis* Glu5' allele from approximately 40% on ropes retrieved in August and September to 80% on the ropes retrieved in October and December (Fig. 3 & 4). In addition, we obtained genotypic data from enough of our collectors in September to allow us to use a 2-way ANOVA to investigate the degree to which the frequency of the *M. edulis* Glu5' allele varies as a function of sampling location and depth. This ANOVA model explained only 43% of the variation in the arcsin-transformed allele frequency for the collectors retrieved from all three sites in September (adjusted $R^2 = 0.43$; $F = 1.21$; $P = 0.37$; Table 4). The low R^2 value indicates that most of the variation in *M. edulis* Glu5' allele frequency occurred among individual rope segments. Not surprisingly, neither the 2-way interaction nor the main effects were significant in this analysis, although it should be

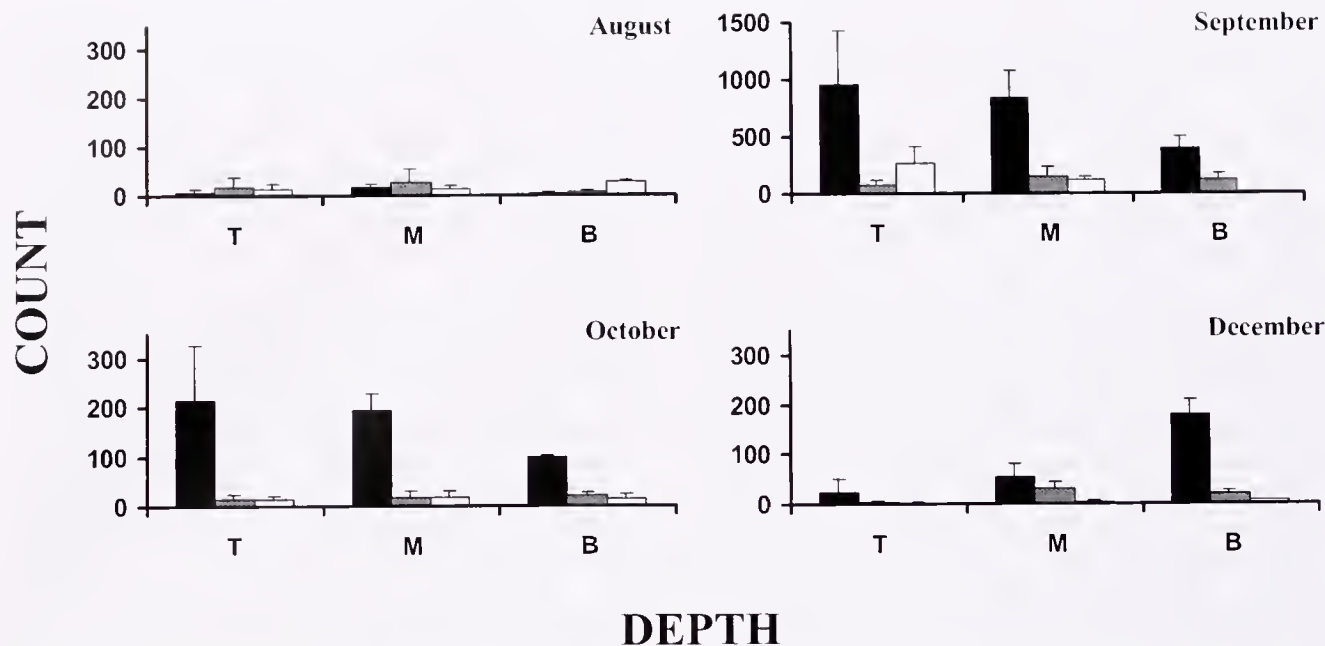

Figure 2. The mean abundance (count) of blue mussel spat (*Mytilus edulis* and *M. trossulus*) on rope collectors at Shackford Head (solid bars), South Bay (grey bars), and East Bay (white bars) as a function of sampling date and depth. Rope collectors were divided into 3 segments, one from 0–1.5 m below the surface (T), a second 1.5–3 m below the surface (M), and the third 3–4.5 m below the surface (B). Error bars represent the mean +1 standard deviation.

noted that this ANOVA had relatively little power to detect such effects (see Table 3).

We used the information from both of our genetic markers to estimate the frequency of individuals with *M. edulis*, *M. trossulus*, and mixed di-locus genotypes. Boecklen and Howard (1997) have shown that at least 4–5 well-differentiated genetic markers are necessary to reasonably estimate the frequency of backcross hybrid genotypes. We successfully genotyped 1200 mussel spat at two diagnostic markers. Though this is too few markers for estimating introgressed genotypes, we can use our genotypic data to roughly classify individuals into *M. edulis*, *M. trossulus* and mixed or hybrid genotypes. The frequency of *M. trossulus* and hybrid genotypes both peaked in September and then declined to around 12% and 4%, respectively, in our October and December samplings (Fig. 5). As expected from the shift in the frequency of the *M. edulis* Glu5' allele frequency, *M. edulis* genotypes were predominant on the collectors retrieved in October and December.

Finally, we used the genotype frequency data to estimate the abundance of *M. edulis* spat at the Shackford Head site as a function of sampling date and depth. The highest abundance of settlers was observed at Shackford Head; however, given the temporal shift in genotype frequencies, the abundance of *M. edulis* settlers remains relatively constant through time (Table 5)

DISCUSSION

The mussel culture industry in Maine currently uses wild caught spat to seed both bottom and off-bottom culture sites. In central Maine, the majority of mussel seed for off-bottom culture originate from the Blue Hill Salt Pond (see Fig. 1). The expense and logistics of seed transfer between central and eastern Maine, as well as concern regarding the potential for disease transfer associated the movement of shellfish between rivers and bays in Maine make it highly desirable to identify a source of mussel seed in eastern Maine. The studies of Freeman (1994) and Mallet and Carver (1995, 1999), however, indicate that the productivity of off-bottom culture operations can be substantially decreased when there is an increased frequency of *M. trossulus* under culture. Given the prevalence of *M. trossulus* adults in Cobscook Bay and well into the Gulf of Maine (Rawson et al. 2001), capitalizing on local sources of seed requires the development of spat collection methods that limit the frequency of *M. trossulus*. For this reason, we investigated species-specific patterns of settlement among the mussel spat settling on our collectors in Cobscook Bay.

Larval settlement in marine benthic invertebrates, particularly those with an extended period of planktonic development, is the result of an interplay between various factors including local and regional hydrodynamics (Pineda 2000, Sponaugle et al. 2002). The morphology of Cobscook Bay together with the large tidal range in the region (>8 m) creates strong directional flows in the main channel of the bay (Brooks et al. 1999). As these tidal flows enter

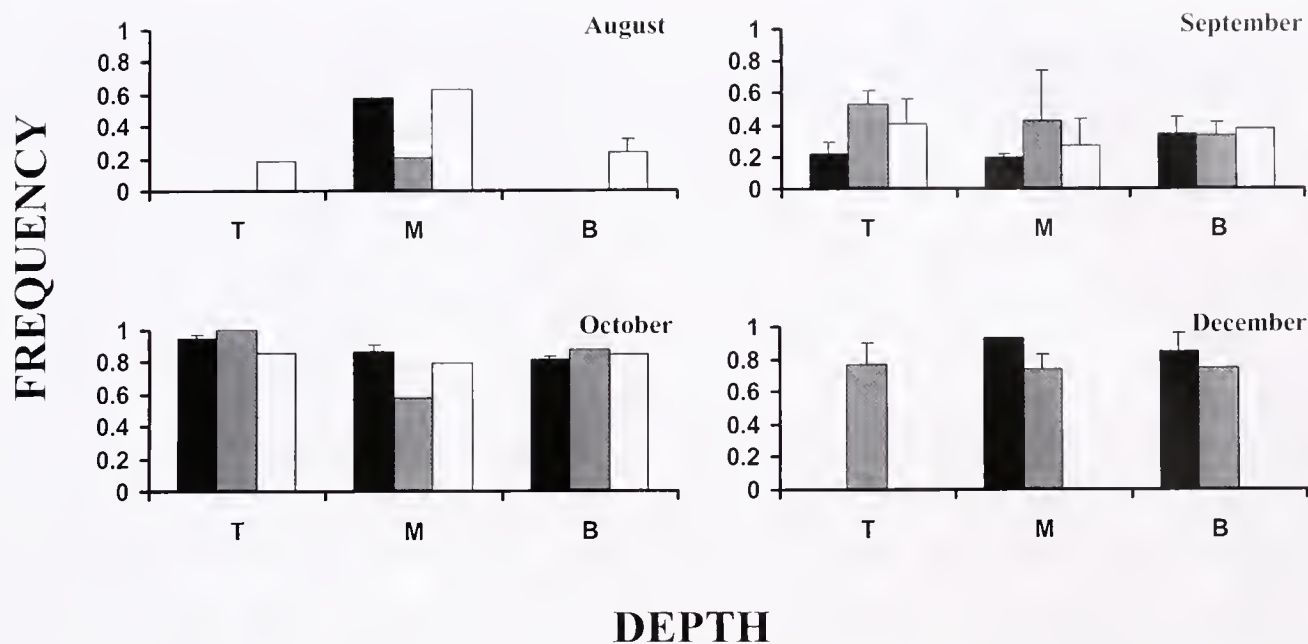

Figure 3. The average frequency of the *M. edulis* Glu5' allele among spat settling at each of 3 collecting sites as a function of sampling date and depth. Depth and location are the same as in Figure 2. Error bars represent the mean ± 1 standard deviation, which were estimated from arcsin-transformed values and then back-transformed for clarity.

the center of the bay, they in turn create an eddy dipole consisting of one clockwise gyre in the southern portion of East Bay and a counter-clockwise gyre in the northern portion of South Bay (Brooks et al. 1999).

Our collectors were deployed near these hydrodynamic features and we anticipated large numbers of mussel postlarvae at all three of our sites. However, we observed substantial variation in mussel settlement among sites. The relatively low settlement on the collectors at our South Bay site was surprising, given that these collectors were placed at a salmon net pen facility within the main current associated with the South Bay gyre. Heavy fouling of the net pens by blue mussels is a continuing problem at this facility (C. Bartlett, personal observation). We can only surmise that because our collectors were downstream of the net pens they were essentially in a settlement shadow. Likewise, the low settlement at our East Bay site suggests a diminished supply of postlarvae. In this case, we feel that our collectors were located further north of the East Bay gyre than we had initially intended.

In contrast, we observed much higher settlement at our Shackford Head site. The value of sites like Shackford Head as a local source of mussel spat within Cobscook Bay, however, is dependent upon the degree to which settlement for *M. edulis* and *M. trossulus* is temporally or spatially segregated. We found no evidence of location-specific variation in the relative abundance of *M. edulis* and *M. trossulus* spat on our collectors. This observation is

consistent with our previous observation that *M. trossulus* adults are highly abundant throughout Cobscook Bay (Rawson et al. 2001). Blue mussels have a planktonic development period that typically lasts 30 days or more and likely results in an open population structure providing little opportunity for spatial variation in the abundance of *M. trossulus* or *M. edulis* larvae to develop.

We found little evidence of depth-specific variation in the abundance of *M. edulis* spat, as well. Low settlement on many of our collectors prevented us from analyzing the effect of depth on

Figure 4. The average frequency of the *M. edulis* Glu5' allele among blue mussel spat settling at all 3 collecting sites and depths combined, as a function of sampling date. Error bars represent the ± 1 standard deviation for the arcsin-transformed values. The lowercase letters above each bar indicate sampling dates for which a *post hoc* test of means (Tukey's) indicated there were significant differences in the mean frequency of the the *M. edulis* Glu5' allele.

the frequency of *M. edulis* markers at all sampling dates. However, depth had no effect on either the frequency of the Glu5' nor the ITS *M. edulis* allele in September when spat abundance on our collectors peaked. The maximum difference between the average depth-specific frequency of the *M. edulis* Glu5' allele was 0.06%. Although the ANOVA testing for depth-specific variation had low statistical power, *post hoc* analysis suggests that even if we had deployed five times as many collectors as we did in this study, the power to detect such small differences would still have been <0.3.

The lack of depth-specific variation in the abundance of *M. edulis* spat was unanticipated, given the recent report by Kenchington et al. (2002). They examined the species-specific patterns of blue mussel settlement at two sites in Nova Scotia and observed consistently higher settlement of *M. edulis* on collectors 4–5 m below the surface. The discrepancy between our study and that of Kenchington et al. (2002) may be due to the different sampling strategies used in each. Kenchington et al. (2002) genotyped mussel spat from collector segments that were 0–1 m, 2–3 m, and 4–5 m below the surface. Thus, our sampling strategy did not extend as deep (only 4.5 m) and our sampling intervals were not as discrete as those of Kenchington et al. (2002). It is interesting to note, however, that Kenchington et al. (2002) observed an increase in the frequency of *M. edulis* spat even at 2–3 m below the surface at their Parrang Cove site (see Fig. 3 in Kenchington et al. 2002). A similar increase in the frequency of *M. edulis* postlarvae below 3 m in Cobscook Bay should have been detected by our methods.

A significant shift in the frequency of *M. edulis* Glu5' and ITS alleles was apparent across sampling dates in our study. The average frequency of these alleles increased from 40% to 45% in August and September to 75% to 80% in October and December. This shift was unexpected, given the overlapping reproductive cycles for *M. edulis* and *M. trossulus* in Cobscook Bay. Maloy et al. (2003) examined the seasonal changes in gamete volume fraction and oocyte diameter for an intertidal population of blue mussels located near our East Bay collectors. They found that maximal gonadal development for both species occurred in mid July followed by a spawning event in late July and early August of 2000. Assuming a 30-d period of larval development, the timing of the spawning event observed by Maloy et al. (2003) correlates well with the peak settlement we observed at our three sites in September. Similarly, Toro et al. (2002) observed overlapping reproductive cycles for *M. edulis* and *M. trossulus* in a sympatric population in Newfoundland. They also noted a protracted period of spawning activity for *M. trossulus* and hybrid mussels. The increase in the frequency of *M. edulis* spat in October and December in our study, however, would suggest a more protracted spawning season for *M. edulis* adults in Cobscook Bay. Interestingly, Maloy et al. (2003)

noted that there was a larger, though not statistically significant, decline in gamete volume fraction for *M. edulis* relative to *M. trossulus* in early September, consistent with a second spawning event for the former species. In addition, histologic analysis on the same specimens indicated that the highest proportion of individuals with undifferentiated gonads occurred from September to December for *M. trossulus* whereas few undifferentiated *M. edulis* were observed until January (Maloy personal communication). These two observations suggest that *M. edulis* is more gametogenically active during the period between September and December in Cobscook Bay. The variation in the frequency of hybrid mussels we observed is also consistent with species-specific temporal variation in spawning activity. The sharp decline in the frequency of *M. trossulus* and hybrid genotypes in our October and December samplings suggests that *M. edulis* continues to spawn after most *M. trossulus* individuals have ceased spawning.

Alternatively, differential mortality in the plankton or during metamorphosis may result in the shift in genotype frequencies we observed. A third potential hypothesis is that the increase in the frequency of *M. edulis* spat on our collectors in October and December is the result of secondary settlement. The former hypothesis requires that both *M. trossulus* and hybrid larvae experience much higher levels of mortality compared with *M. edulis* during October and November whereas the latter hypothesis requires that there be substantial genotype-specific behavioral differences among recently settled mussels. Presently, there is little comparative data on the larval physiology or behavior of *M. edulis*, *M. trossulus*, and their hybrids, so at present we favor the hypothesis that species-specific variation in spawning activity produces the temporal shift to higher frequencies of *M. edulis* spat.

Finally, our data have important implications for the potential establishment of off-bottom culture of blue mussels in Cobscook Bay. The results we have presented suggest that the deployment of spat collectors from October through December could result in >80% *M. edulis* spat. Three important caveats, however, accompany this observation. First, our sampling was confined to a single year and without additional sampling it is impossible to tell whether the increase in *M. edulis* spat late in the year will hold in other years. Second, the overall abundance of spat decreased dramatically on the collectors we retrieved in October and December so

Figure 5. The average frequency of *M. edulis* (light grey), hybrid (dark grey), and *M. trossulus* (white) dilocus genotypes as a function of sampling date. Error bars represent the mean +1 standard deviation which were estimated from arcsin-transformed values and then back-transformed for clarity.

TABLE 5.

The number of mussel spat observed on top, middle, and bottom rope segments at Shackford Head, Cobscook Bay across 4 collection dates in 2000. For comparison to the data of Kenchington et al. (2002) the numbers are expressed on a per meter basis. N_{total} represents the number of all mussel spat per meter of rope. The number of *M. edulis* ($N_{M. edulis}$) versus *M. trossulus* and hybrid spat (N_{other}) was estimated using the frequency of individuals with *M. edulis* di-locus genotypes at the Glu5' and ITS markers.

Month	Depth	N_{total}	% <i>M. edulis</i>	$N_{M. edulis}$	N_{other}
August	Top	5	—		
	Middle	10	40.1	4	6
	Bottom	3	—		
September	Top	638	10.3	64	574
	Middle	560	23.9	129	431
	Bottom	260	25.2	65	195
October	Top	143	90.4	129	14
	Middle	129	79.7	103	26
	Bottom	66	74.5	50	17
December	Top	16	95.0	15	1
	Middle	35	89.6	32	4
	Bottom	118	74.2	87	31

that even Shackford Head, the best of our three sites, may not receive enough spat to seed commercially viable culture facilities. Third, spat setting later in the year are likely to realize low growth rates and potentially high mortality due to declining water temperatures. Given these caveats, reliance on spat collected late in the year would appear to be a risky strategy. The consistently high frequency of *M. trossulus* spat at all three sites and depths in September, when peak settlement occurs, would seem to preclude the development of site- or depth-specific methods for the collection of *M. edulis* spat as well as the deployment of *M. edulis* seed from external sources up to October. Thus, our results indicate that there are likely to be significant obstacles limiting the preferential collection and cultivation of *M. edulis* mussels in Cobscook Bay.

LOCALIZED SYNCHRONOUS SPAWNING OF *MYTILUS CALIFORNIANUS* CONRAD IN BARKLEY SOUND, BRITISH COLUMBIA, CANADA

LOUIS A. GOSSELIN

Department of Biological Sciences, University College of the Cariboo, Kamloops B.C., Canada and Department of Biology, University of Victoria, Victoria B.C., Canada

ABSTRACT Although *Mytilus californianus* is a dominant intertidal species along most exposed rocky shores of the northwest coast of North America and has been studied extensively, no direct observations of spawning by this species in the field have been reported. This paper presents the first report of synchronous spawning in the field by the mussel *M. californianus*. Two synchronous spawning events were observed in Barkley Sound on the west coast of Vancouver Island, British Columbia, Canada. On both occasions several thousand mussels spawned profusely at low tide, leaving masses of gametes on their shells or concentrated in tidepools and surge channels. In the 2002 spawning event 35% of the mussels spawned, for an estimated 54,000 spawning mussels, and fertilization rate in a surge channel was ~80%. Both spawning events, however, were highly localized, occurring within 24–41 m lengths of shoreline; no mussels spawned along adjacent areas of the shore. The timing of these 2 spawning events showed no consistent relationship with tidal and lunar phases, seawater temperature or cloud cover, and mussels in adjacent parts of the shoreline did not release gametes when exposed to spawned material. Localized synchronous spawning might be common in *M. californianus*, involving a patchwork of spawning events occurring intermittently over periods of a few months or throughout the year. This could provide the benefits of synchronous spawning as well as the advantages of the continuous production of recruits.

KEYWORDS: life cycle, reproduction, fertilization rate, gametes, broadcast spawning, *Mytilus*

INTRODUCTION

Among aquatic organisms, the synchronous release of gametes or larvae by many individuals of a population can provide increased fitness (see review by Olive 1992) by enhancing fertilization rates in broadcast spawners (Pennington 1985, Babcock 1995), taking advantage of hydrodynamic conditions that optimize fertilization or dispersal (Pennington 1985, Olive 1992), reducing larval mortality by predator satiation (Harrison et al. 1984, Slattery et al. 1999), and synchronizing the timing of planktotrophic larval development with that of algal blooms which the larvae use as food (Starr et al. 1990). Knowledge of whether a species spawns synchronously is therefore important in elucidating its population dynamics. In addition, an understanding of how environmental factors influence the timing of spawning can help predict future spawning events or determine how changes in environmental conditions can affect reproductive success (Minchin 1992, Olive 1992, Watson et al. 2000).

Synchronous spawning has most commonly been reported in anthozoans (Harrison et al. 1984, Babcock et al. 1986, 1992, Brazeau & Lasker 1989) and various echinoderms (Pearse et al. 1988, Babcock et al. 1992, Lamare & Stewart 1998) but also occurs in other marine invertebrates such as bivalves (Babcock et al. 1992, Minchin 1992, Grant & Creese 1995), gastropods (Counihan et al. 2001) and polychaetes (Caspers 1984, Hardege 1999, Watson et al. 2000). Sightings of natural spawning, however, are most often chance observations and, as a result, many species that do spawn synchronously may simply not yet be known to do so. This paper reports the first observations of synchronous spawning by the mussel *Mytilus californianus*.

Mytilus californianus is a dominant intertidal species on exposed rocky shores along the northwest coast of North America, forming extensive mussel beds from British Columbia to California (Suchanek 1981). Studies based on gonad condition or laboratory spawning indicate that this species is capable of spawning throughout the year (Young 1945, Kelly et al. 1982, Dittman & Robles 1991) and that the peak spawning period in British Colum-

bia occurs in the summer (Kelly et al. 1982). A study of male gonad development in *M. californianus* in British Columbia concluded that many individuals are trickle-spawners (Kelly et al. 1982). However, no direct observations of spawning by this species in the field have been reported. This paper (1) reports 2 synchronous spawnings by *Mytilus californianus*, one in 1992 and the other in 2002, (2) quantifies the spawning rate and fertilization rate for the 2002 event, and (3) examines the relation of these 2 events with tidal, lunar, seawater temperature and cloud cover conditions.

METHODS AND RESULTS

The 2 spawning events described herein occurred in Barkley Sound on the west coast of Vancouver Island, British Columbia, Canada, and were discovered while visiting the sites at low tide. Tide levels for periods when the spawning events occurred were obtained from the Canadian Hydrographic Service (1991, 2001) tide tables. Surface seawater temperature data for Cape Beale (48°47'20"N, 125°12'95"W) and Amphitrite Point (48°55'25"N, 125°32'50"W), for 1992 and 2002, were obtained from the Fisheries and Oceans Canada online database for BC lighthouses (http://www-sci.pac.dfo-mpo.gc.ca/osap/data/SearchTools/SearchLighthouse_e.htm). Amphitrite Point data was used for 2002 because seawater temperature measurements at Cape Beale ended in 1998.

1992 Spawning Event

The first spawning event was observed at Kirby Point (48°50'85"N, 125°21'40"W) on 22 June 1992. A large number of mussels had spawned profusely and several tidepools were clouded with sperm and lined with a coating of orange oocytes. Mussels outside of tidepools had masses of gametes on their shells near the siphons. Spawning was limited to a 24 m section of shoreline in which the mussel bed ranged in width from 3.0 m

to 14.5 m; the surface area within which spawning occurred was $\sim 214 \text{ m}^2$. No spawning mussels were found within 100 m on either side of the spawning area. In addition, to determine if spawning was stimulated by exposure to spawned material from other mussels, 3–4 l of water from a tidepool with an abundance of spawned material was transferred to each of 3 other small tidepools several metres away, in which no spawned material was apparent. Each tidepool contained 10–30 mussels. No spawning was observed over the following 2 h in the 3 tidepools receiving spawned material. This spawning event occurred at a time when the tidal amplitude was modest (Fig. 1A), with the moon in its last quarter. The weather that morning was sunny, and surface seawater temperature had been increasing for over 2 weeks (Fig. 1B).

2002 Spawning Event

The second spawning event was observed during a collecting trip to the intertidal zone at Cape Beale on the morning of 8 August 2002. Large numbers of emersed mussels were found with masses of gametes at the margin of their shell near the siphons. The water in several small tidepools as well as in a surge channel running parallel to the shoreline was yellowish-brown from the high densities of gametes. This spawning event occurred during very high amplitude tides (Fig. 2A) at new moon. The weather that morning was overcast, and surface seawater temperature had

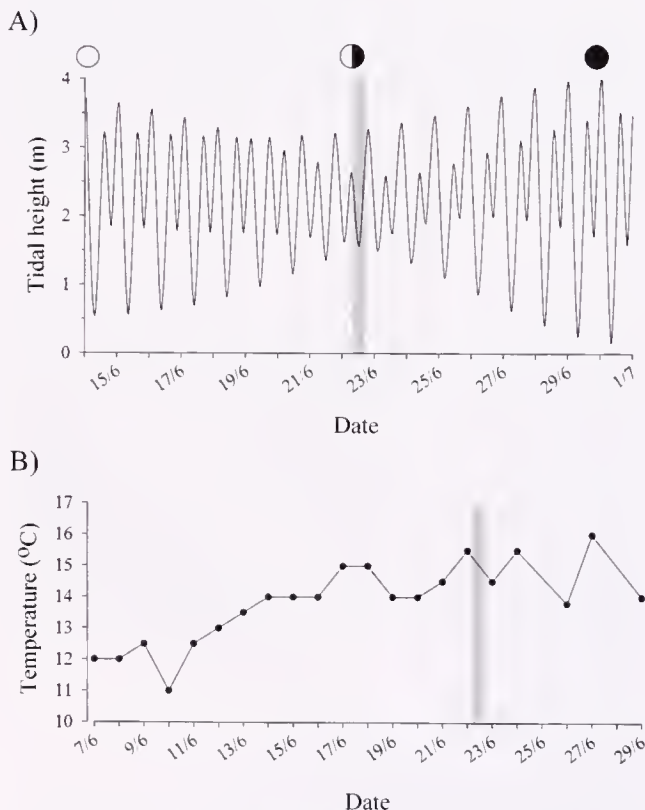

Figure 1. Environmental conditions prior to and after the synchronous spawning event of *Mytilus californianus* in 1992. The dashed areas in each graph represent the time of the spawning event. (A) Tidal heights and lunar phases; (B) surface seawater temperatures measured at the Cape Beale lighthouse.

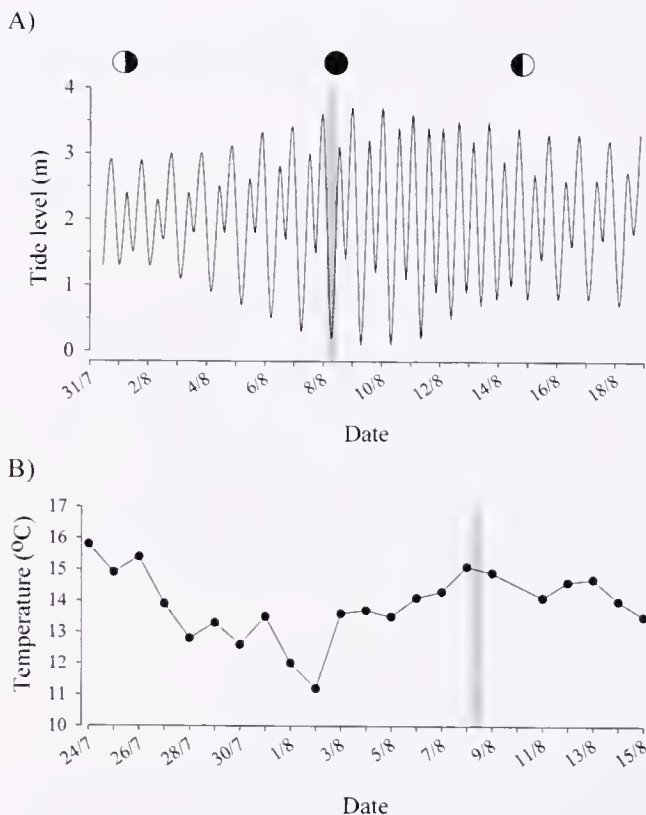

Figure 2. Environmental conditions prior to and after the synchronous spawning event of *Mytilus californianus* in 2002. The dashed areas in each graph represent the time of the spawning event. (A) Tidal heights and lunar phases; (B) surface seawater temperatures measured at the Amphitrite Point lighthouse.

been relatively stable over the 5d preceding the spawning event, with a slight increase on the day of spawning (Fig. 2B). To further characterise the event 4 sets of observations and measurements were taken.

Mussel Densities and Proportion of Mussels that Spawning

To quantify mussel densities and the proportion of mussels that spawned, observations were made along 2 separate transects running parallel to the shoreline within the mussel bed. Each transect consisted of five $25 \times 25 \text{ cm}$ quadrats set at 1 m intervals. In each quadrat I counted the total number of visible mussels and the number of mussels having spawned to determine the proportion of mussels that had spawned. Spawned gametes, when present, were located at the margin of the shell near the siphons or, when located elsewhere on the shell, a shiny slime coating could be observed running from the shell margin to the spawned material. Mussels were not dislodged for these observations; if small juvenile mussels were present deeper within the mussel bed they would not have been detected. *Mytilus californianus* densities in individual quadrats within the mussel bed ranged from 392 to 984 mussels m^{-2} and averaged 678 mussels m^{-2} (Table 1). Although densities varied among the 2 transects, the proportion of *M. californianus* that had spawned was consistent, averaging $\sim 35\%$ in each transect. No spawned material was present on low intertidal mussels that were exposed to wave wash, but the abundant gametes in the nearby water indicated that many of these had also spawned.

TABLE 1.

Mytilus californianus. Densities and percent of mussels found to have spawned at Cape Beale on 8 August 2002.

	Mussel Density m^{-2} (\pm SD)	% Spawned (\pm SD)
Transect 1	520.0 \pm 119.6	33.0 \pm 15.4
Transect 2	836.8 \pm 122.45	36.1 \pm 4.8
Overall	678.4 \pm 202.2	34.51 \pm 10.9

Smallest Spawning Mussel

The mussel bed was closely examined for 15 minutes to search for and measure the smallest mussels with spawned material. The smallest spawning mussel measured 28 mm shell length, which is within the reported size range (25–30 mm) at which *Mytilus californianus* reaches maturity (Suchanek 1981). Several 30–50 mm mussels had also spawned. Mussel sizes at that site ranged from 10.2 mm to 150.0 mm, with most mussels measuring 60 mm to 120 mm. Few were smaller than 30 mm. The spawning event thus appears to have included all mussel sizes present in the bed.

Number of Mussels Spawning

Mussels with spawned gametes were found only along a 41 m section of shoreline. The width of the mussel bed along that section of shoreline ranged from 1.8 m to 14.2 m, for a surface area of the bed where spawning occurred of $\sim 231 \text{ m}^2$. No spawning mussels were found over $\sim 100 \text{ m}$ on either side of the spawning area. Using an average mussel density of 678.4 m^{-2} and an average of 34.51% of mussels spawning (Table 1), the total number of mussels spawning in this event is estimated at 54,080 individuals.

Oocyte and Egg Density and Percent Fertilization in a Surge Channel

The combined density of oocytes and eggs as well as percent fertilization was determined by collecting a 60 ml sample of seawater from a surge channel formed by a rocky outcrop running parallel to the shoreline. The swell entering the channel caused continuous and substantial turbulence, thoroughly mixing the water throughout the channel. Oocytes and eggs were counted in the laboratory within five 0.1 ml subsamples. In addition, I estimated the proportion of oocytes that had been fertilized from the proportion that had undergone cleavage at 1:15 PM the same day, approximately 5–10 h after they had been spawned. Combined oocyte and egg density in the channel running parallel to the mussel bed was $885 \pm 80.1 \text{ ml}^{-1}$ (average \pm SD). Based on measurements of length, width and depth of the channel, the volume of water in the channel at the time the sample was taken was estimated to be $\sim 60,800 \text{ l}$. Using 885 eggs ml^{-1} as an estimate of density throughout the channel, the water in that channel would have contained $\sim 5.4 \times 10^{10}$ oocytes and eggs. In the sample returned to the laboratory, $80.7 \pm 12.3 \%$ (average \pm SD) of these developed at least to the 2-cell stage. Using 80.7% as an estimate of fertilization rate, the channel would have contained $\sim 4.3 \times 10^{10}$ fertilized eggs. This constitutes the output of only the lower part of the mussel bed, as approximately two-thirds of the mussel bed was above the splash zone at the time of sampling and the gametes produced by those mussels were not suspended until later by the rising tide.

DISCUSSION

Localized Synchronous Spawning in *Mytilus californianus*

Mytilus californianus have the capacity to spawn at any time of the year (Young 1945, Kelly et al. 1982, Smith & Strehlow 1983, Dittman & Robles 1991). It has also been suggested, based on observations of juvenile recruitment throughout the year, that *M. californianus* spawns continually releasing small amounts of gametes throughout the year (Suchanek 1981) and a study of gonad condition in male mussels revealed that about half of the males are probably 'trickle' spawners (Kelly et al. 1982). None of these conclusions, however, are based on observations of spawning in the field. Despite its widespread occurrence and ecological importance along the rocky shores of the northwest coast of North America, there are no reports of *M. californianus* spawning in the field. In the present study, more than 50,000 mussels spawned in the 2002 event. Mussel densities were not quantified in 1992; however, assuming an average density similar to that observed at Cape Beale in 2002 of $678.4 \text{ mussels m}^{-2}$, the total number of mussels in that section of mussel bed would have been $\sim 145,000$ individuals. The number of mussels spawning in the 1992 event was thus likely in the order of several thousand. These findings reveal that events in which large numbers of individuals spawn synchronously do occur in this species. This is the first report of synchronous spawning in *M. californianus* and the first such report for a species in the genus *Mytilus*.

The 80.7% fertilization rate observed during the 2002 spawning event is consistent with the expectation that synchronous spawning in a population favours high fertilization rates (Pennington 1985, Olive 1992, Babcock 1995). This particularly high fertilization rate, however, was possibly due to the retention and continuous mixing within the limited volume of the surge channel, as fertilization rate should decrease with dilution of the gametes (Pennington 1985, Levitan et al. 1992). Particularly intriguing, however, is the fact that both spawning events were very localized. While a high proportion of mussels in a given area of shoreline spawned, mussels in adjoining areas of the shoreline did not. The boundary between spawning and non-spawning areas of the mussel bed occurred over 1–2 m, and there was no apparent physical difference in the shoreline or in the size or health of the mussels between areas with and without spawning mussels.

In addition, it is not clear why the mussels spawned at low tide; why not release the gametes at high tide when fully submerged? One might expect the viability of gametes released at low tide to be decreased due to exposure to air and ultraviolet radiation. Given the rarity of observations of spawning by *Mytilus californianus* in the field, it may be that spawning usually takes place at high tide and that low tide spawning events are rare occurrences.

Factors Influencing Spawning Synchrony

Several factors have been reported to induce or synchronize spawning in marine invertebrates, including tidal and lunar phases (Caspers 1984, Babcock et al. 1986, Slatery et al. 1999, Watson et al. 2000), changes in seawater temperature (Minchin 1992), mechanical stimulation by water flow (Desrosiers & Dubé 1993) or by wave action (Young 1945), clement weather (Watson et al. 1986), and water-borne chemicals released by other spawning individuals (Young 1945, Atkinson & Atkinson 1992, Hardege

1999) or by phytoplankton (Breese & Robinson 1981, Smith & Strehlow 1983, Starr et al. 1990, Parsons et al. 1992). The present study therefore documented tidal and lunar phases, seawater temperature (measured 1–3 km from the spawning sites) and weather (cloud cover) to determine if the 2 spawning events occurred under similar conditions. None of these factors, however, were the same on both spawning events. Finally, water transferred from tidepools with spawned gametes to tidepools in which mussels had not spawned did not induce spawning, although it is possible that those mussels had spawned on previous days and thus were unable to spawn that morning.

Ecological Significance of Synchronous Spawning by *Mytilus californianus*

Observations of the two spawning events described herein were serendipitous. I have frequently visited various rocky intertidal sites colonized by *Mytilus californianus* in Barkley Sound over the last 14 years but only observed mussels spawning on these 2 occasions. These observations nevertheless reveal that synchronous spawning of several thousand *M. californianus*, and by as much as 35% of the individuals of a mussel bed, does occur. It may be that such events are not rare, but happen mostly at night or when

the mussels are submerged, and therefore spawning goes unnoticed. If localized synchronous spawning is common in *M. californianus*, reproduction in this species could involve a patchwork of spawning events occurring intermittently over periods of a few months or throughout the year, which would be consistent with Suchanek's (1981) observations of recruitment throughout the year on the northern coast of Washington State. This strategy would allow the species to benefit from the advantages of synchronous spawning as well as from the continued production of recruits allowing the opportunistic colonization of habitats as they become available, free space being a limiting resource on these exposed rocky shores, made periodically available by disturbance events such as storms and impacts by floating logs (Dayton 1971, Paine 1974).

ACKNOWLEDGMENTS

Thanks to the director and staff of the Bamfield Marine Sciences Centre for research facilities and support. Thanks to E. G. Boulding, C. Robles and two anonymous reviewers for reading and commenting on earlier versions of the manuscript and to Carla Gibbons for assistance in the field. MINI-REVIEW: DISTRIBUTION OF THE MEDITERRANEAN MUSSEL *MYTILUS GALLOPROVINCIALIS* (BIVALVIA: MYTILIDAE) AND HYBRIDS IN THE NORTHEAST PACIFIC

MARJORIE J. WONHAM*

University of Washington, Department of Zoology, Box 351800, Seattle, WA, USA 98195-1800

ABSTRACT The non-native Mediterranean mussel *Mytilus galloprovincialis* is broadly established in the northeast Pacific. Until recently, the coast north of Humboldt Bay, California, USA, was not considered a major zone of sympatry and hybridization with the native sibling species *M. trossulus*. However, *M. galloprovincialis* has been introduced in Washington, USA, and British Columbia, Canada, for aquaculture, has been collected from ballast water in-bound to Oregon, USA, and is now reported widely in Puget Sound, Washington. Here I review published reports of *M. galloprovincialis* alleles in the Northeast Pacific, including recent data showing that these alleles are more widespread and abundant in Washington than previously known. These results indicate the presence of a major zone of sympatry and hybridization in Washington waters that may be contiguous with the California zone. Because *M. galloprovincialis* has likely been introduced to the region on multiple occasions via multiple routes, it is unlikely that a sole source can be identified. Factors influencing the success and impacts of this now widespread invader remain to be investigated.

KEY WORDS: introduced marine species, hybridization, Pacific Northwest, *Mytilus galloprovincialis*

INTRODUCTION

The marine mussel genus *Mytilus* includes a complex of 3 sibling species, *M. edulis* L. 1758, *M. trossulus* Gould 1850, and *M. galloprovincialis* Lamarck 1819. All three are now globally widespread and form hybrid zones where they overlap (McDonald et al. 1991, Sarver & Foltz 1993, Hilbish et al. 2000). The role of human activity in establishing the global but disjunct distributions of these species has been addressed in terms of genetic evidence, fossil evidence, and the available introduction pathways. (e.g., McDonald et al. 1991, Carlton 1999, Daguin & Borsa 2000, Hilbish et al. 2000)

Certain features of *Mytilus* species make them likely candidates for human-mediated introduction: their planktonic larval stage allows them to be passively transported in the ballast water of commercial ships (e.g., Carlton & Geller 1993), byssal threads produced by juveniles and adults allow transport on hard substrata including ship and boat hulls (Carlton & Hodder 1995, Apte et al. 2000), and their palatability and relative ease of culture has led to their widespread introduction for aquaculture (Heath et al. 1995, Couturier 2003 and references therein).

M. galloprovincialis is the most widely distributed of the three sibling species, and recent genetic analyses distinguish among multiple hypotheses for its origin and spread (Daguin & Borsa 2000). In the Northeast Pacific, *M. galloprovincialis* ranges from Mexico to central California, and recent surveys confirm its presence throughout the inner waters of Washington State (Suchanek et al. 1997, Anderson et al. 2002, present study). The origin, timing, and pathways of its introduction to Washington remain unclear, and it has likely been introduced on multiple occasions. Here, I summarize recent genetic analyses of *Mytilus* spp. distributions globally and in the northeast Pacific, provide additional sampling results from Washington State waters, review our current understanding of the *M. galloprovincialis* introduction to the region, and identify ecologic questions to be addressed concerning this introduction.

Global *Mytilus* Distributions

Because *Mytilus* sibling species and their hybrids cannot reliably be distinguished with morphologic characters alone, genetic analysis is required to determine their distributions and origins. *M. edulis* and *M. galloprovincialis* are the most closely related and *M. trossulus* is the most divergent according to genomic DNA (Beynon & Skibinski 1996, Eirin-Lopez et al. 2002, Martínez-Lage et al. 2002) and mtDNA analysis (Rawson & Hilbish 1995b, Quesada et al. 1998, Geller 1999, Hilbish et al. 2000). Two additional studies report evidence that may suggest that *M. galloprovincialis* is the most divergent of the three species (Wenne & Skibinski 1995, Varvio et al. 1988). However, the mtDNA-based species determinations in one study (Wenne & Skibinski 1995) may have been confounded by sex-specific differences, and the other study stated clearly that their allozyme analysis should not be taken to indicate relative relatedness among the species (Varvio et al. 1988).

The three sibling species have distinct but overlapping distributions. *M. trossulus* is circumpolar in the north Pacific, northwest Atlantic, and Baltic, but has not been unambiguously identified in the southern hemisphere (McDonald et al. 1991, Hilbish et al. 2000). *M. edulis* is found in the northeast and northwest Atlantic, and *edulis*-like mussels are reported from South America (McDonald et al. 1991). *M. edulis* has also been introduced to British Columbia for aquaculture (Heath et al. 1995). *M. galloprovincialis* is distributed throughout the Mediterranean and into the northeast Atlantic, with additional populations in California, Japan, South Africa, Australasia and Chile (McDonald et al. 1991, Sanjuan et al. 1997, Daguin & Borsa 2000, Hilbish et al. 2000). To account for its disjunct distribution, *M. galloprovincialis* has been proposed variously to be endemic to the Mediterranean and introduced in the north and south Pacific (Barsotti & Meluzzi 1968, McDonald et al. 1991, Carlton 1999), possibly endemic to the south Pacific (Koehn 1991, McDonald et al. 1991), and endemic to both the Pacific and Mediterranean (Sanjuan et al. 1997). These alternate hypotheses are comprehensively reviewed by Daguin and Borsa (2000) and Hilbish et al. (2000); the key points are summarized here.

Northern hemisphere populations of *M. galloprovincialis* in the Atlantic and the Mediterranean can be distinguished by allozyme (Quesada et al. 1995b, Sanjuan et al. 1997) and mtDNA analysis

*Corresponding author. E-mail: mwonham@ualberta.ca

(Quesada et al. 1995a, Quesada et al. 1998, Ladoukakis et al. 2002). The Californian population is more closely related to the Mediterranean than to the Atlantic population in allozyme (McDonald & Koehn 1988, Sanjuan et al. 1997) and genomic DNA studies (Daguin & Borsa 2000). In the southern hemisphere, *Mytilus* sp. appear in fossil beds and middens, and genomic DNA analysis indicates that present-day populations are closest to, but readily distinguished from, Mediterranean populations (Daguin & Borsa 2000, Hilbish et al. 2000).

The emerging evolutionary and historical picture that appears most consistent with genetic and geological data is that the genus *Mytilus* evolved in the north Pacific, that the *M. trossulus* stock migrated ~3.5 mya through the Bering Strait to the north Atlantic where the *M. edulis* stock arose, and that *M. galloprovincialis* subsequently diverged from *M. edulis* in the Mediterranean (Vermeij 1991, 1992; Daguin and Borsa 2000; Hilbish et al. 2000). Subsequently, both *M. galloprovincialis* and *M. edulis* migrated to the southern hemisphere (Vermeij 1991, 1992, Daguin & Borsa 2000, Hilbish et al. 2000). Since these early natural dispersal events, more recent translocations have occurred to California, southern Africa, and the northwest Pacific (Wilkins 1983, Grant & Cherry 1985, Lee & Morton 1985, McDonald & Koehn 1988, Inoue et al. 1997, Sanjuan et al. 1997, Daguin & Borsa 2000). Because none of these introductions is known to have been intentional, they most likely occurred accidentally via commercial shipping transport. *Mytilus* species may also have been recently transported to the southern hemisphere by shipping; this remains to be determined.

Northeast Pacific *Mytilus*

The broad-scale distribution of *Mytilus* species along the Pacific coast of North America is well established. *M. trossulus* is currently found from Alaska south to Monterey Bay, California (~36°N) and *M. galloprovincialis* from Mexico north to Humboldt Bay, California (~38°N). An apparently stable hybrid zone extends between San Diego (~32°N) and Humboldt Bay (McDonald & Koehn 1988, McDonald et al. 1991, Sarver & Foltz 1993). The congener *M. californianus* is a morphologically, genetically, and ecologically distinct species that is found on exposed shores along the entire coast (Sarver & Foltz 1993); it is not treated further here.

Until recently, only a handful of *M. galloprovincialis* and hybrids had been collected from Oregon to British Columbia, and the coastline north of Humboldt Bay was not considered a major zone of sympatry and hybridization (Heath et al. 1995, Rawson & Hilbish 1995a, Suchanek et al. 1997, Rawson et al. 1999). However, *M. galloprovincialis* has been widely introduced for aquaculture in Washington and British Columbia, and *M. edulis* to a lesser extent in British Columbia (Brooks 1991, Heath et al. 1995, Hilbish 1999, Anderson et al. 2002). In addition, *M. galloprovincialis* has been identified in ballast water loaded in Japan and scheduled for discharge in Oregon (Carlton & Geller 1993, Geller et al. 1994, Suchanek et al. 1997). Given the large scale of both aquaculture and ship-mediated invasion pathways in the Pacific Northwest (Wonham & Carlton 2004), we might expect *M. galloprovincialis* (and possibly *M. edulis*) to be more widely distributed in these waters. Indeed, recent surveys of Puget Sound and the Strait of Juan de Fuca, Washington, indicate that *M. galloprovincialis* alleles are distributed broadly in the south and central sound and in the Strait of Juan de Fuca (Anderson et al. 2002, present study). Along the outer coast, *M. galloprovincialis* is reported from north-

ern California and Oregon, but seems to be largely absent from Washington (Suchanek et al. 1997, Brooks 1991). Northeast Pacific records of *M. galloprovincialis* and hybrids are detailed here by province and state.

British Columbia

Heath et al. (1995) sampled 12 sites on Vancouver Island and the adjacent mainland (Fig. 1, Table 1). They found non-native alleles belonging to either *M. galloprovincialis* or *M. edulis* at five sites from Yellow Island to Victoria. Because mussel aquaculture is continuing to develop in BC, new surveys in this region using species-specific markers are welcome.

Washington

The subtidal distribution of *M. galloprovincialis* alleles in Washington extends throughout the Strait of Juan de Fuca, the North Puget Trough, and Puget Sound (Fig. 2, see Table 1). *M. galloprovincialis* was identified as early as 1988 in the eastern strait (Brooks 1991), and extensive sampling in the straits and Puget Sound indicates it is now ubiquitous in this region (Anderson et al. 2002, present study). It has been found in the East, Main, and South Basins of Puget Sound, but not in Hood Canal, and appears less frequently in Northern Puget Trough (see Fig. 1, Table 1). Brooks (1991) found no *M. galloprovincialis* on the outer coast of Washington; one hybrid was reported from Tatoosh Island by Suchanek et al. (1997) but none was found there in recent sampling (present study; see Fig. 1, Table 1).

In this study, I made 16 collections totaling 390 individual *Mytilus* at 15 Washington sites from 1997 to 2000 (see Table 1). Subtidal mussels were collected by hand from public docks and marinas and one aquaculture farm. Ten of the docks and marinas were sampled during a rapid-assessment survey for introduced marine species (Cohen et al. 1998), and an additional four were sampled along the northern Olympic peninsula (see Fig. 1, Table 1). At each site, up to 15 mussels were collected by hand from underneath floating docks. Mussels were selected haphazardly, but because they were collected as visible and accessible among other fouling species, they tended to be large (all 3–10 cm long). Mussels in the same size range were also collected from suspended culture ropes at Taylor United Shellfish farm, Shelton, Washington. These included both cultured mussels (i.e., *M. galloprovincialis* seeded from hatchery stock) and natural-set mussels (see Table 1). Intertidal mussels (1–3 cm shell length, representing the largest mussels at the site) were collected from the rocky shores of Tatoosh Island at the entrance of the Strait of Juan de Fuca, and Saddlebag Island in Padilla Bay (see Fig. 1, Table 1). All specimens were stored at -10°C until identification.

Mussels were dissected and DNA was extracted from 0.5 g of gonad tissue following Geller et al. (1994). Polymerase chain reaction (PCR) amplification followed Suchanek et al. (1997) using the species-specific primers developed by Inoue et al. (1995). The PCR product was run on a 2% agarose gel: individuals homozygous for this marker exhibit a single band and heterozygotes exhibit bands of both parental species (Inoue et al. 1995, Suchanek et al. 1997, Wonham 2001). All heterozygotes are *M. galloprovincialis* x *M. trossulus* hybrids, whereas homozygotes may represent either pure or introgressed genomic DNA strains. Although introgression seems to be limited in these populations (Rawson et al. 1999), heterozygote frequencies nonetheless probably underestimate the relative abundance of hybrids. Reference DNA samples

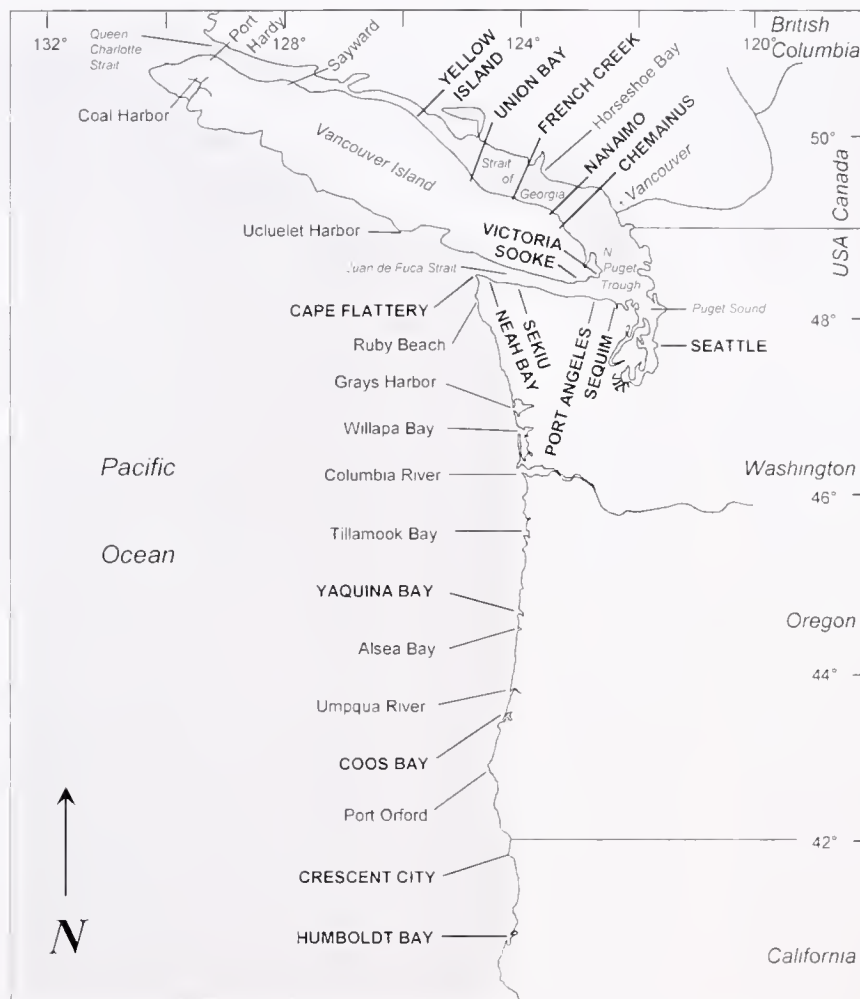

Figure 1. *Mytilus* spp. sampling sites along the Pacific coast. Sites where *M. galloprovincialis* genes were detected indicated in bold capitals. Sites where only *M. trossulus* genes were detected indicated in regular type. Landmarks indicated in italics. For details see Table 1.

for each species were provided by J. Mitton, University of Colorado. For further collection and analysis details see Wonham (2001).

I found *M. galloprovincialis* genes in subtidal mussel samples throughout Puget Sound, the Strait of Juan de Fuca, and northern Puget Trough. Homozygote *M. galloprovincialis* and heterozygotes were present at 4/4 marinas along the Strait of Juan de Fuca, and 6/8 marinas in Puget Sound (Figs. 1 and 2, see Table 1). Together they averaged of 22% of mussels in both regions (range 0% to 50% in the strait and 8% to 54% in the sound, excluding aquaculture samples). They were present at only one site in northern Puget Trough (see Fig. 1, Table 1).

This Puget Sound and Trough distribution of *M. galloprovincialis* is largely consistent with that found by Anderson et al. (2002), who sampled similar locations. Differences are that I found *M. galloprovincialis* alleles at Steilacoom and Elliott Bay Marinas where they did not, but not at Seattle (Harbor Island Marina) or Tacoma (Ole and Charlie's Marina), where they did. I take these minor differences between studies to indicate local spatial heterogeneity in mussel species distributions: with larger sample sizes at identical sites the results would likely be consistent.

The frequency of *M. galloprovincialis* genes (22%) exceeds previous estimates for Puget Sound by approximately 4-fold

(Brooks 1991, Suchanek et al. 1997, Anderson et al. 2002, cultured mussels excluded from all studies). Because my collections and those of Anderson et al. (2002) were made in the same year, the difference does not reflect a temporal change. Instead, I suggest that it may reflect differences in the size of sampled mussels. The subtidal mussels I collected were 3–10 cm in shell length, whereas those analyzed by Anderson et al. (2002) were as small as 0.5 cm. Further evidence for a difference in sizes is found in the detailed analysis by Anderson et al. (2002) of mussels at one site, where they found that smaller mussels had predominantly *M. trossulus* alleles and larger ones had predominantly *M. galloprovincialis* alleles. The potentially larger size of *M. galloprovincialis* has implications for the invader's fecundity and spread relative to its native sibling species.

Although *M. galloprovincialis* was readily found at subtidal sites, I found none in intertidal samples from Tatoosh Island. Because *M. galloprovincialis* is common at other intertidal sites in the Pacific and Atlantic (Sarver & Foltz 1993, Quesada et al. 1995b, Rawson & Hilbish 1995a, Wilhelm & Hilbish 1998), it seems likely that it will also invade this habitat in Washington waters. On the other hand, at one site in Posjet Bay, Russia, McDonald et al. (1991) found exclusively *M. trossulus* intertidally and exclusively *M. galloprovincialis* subtidally. Only one intertidal hybrid has

TABLE 1.

Mussel *Mytilus* spp. records on the Pacific coast of North America from Queen Charlotte Strait, British Columbia, to Humboldt Bay, California. For each site, proportion of, homozygous *M. galloprovincialis* alleles, Mg, homozygous *M. trossulus* alleles, Mt, and heterozygous hybrids, Mg × Mt, given. N, number of individuals sampled. Sites in bold are those with *M. galloprovincialis* or hybrid individuals; p, genes present but not quantified; nd, data not provided in original study; –, marker could not distinguish heterozygotes. Latitude (°N), longitude (°W), and sampling date (m/yy) given for intertidal and subtidal mussel *Mytilus* spp. collection sites in the present study; sites indicated with * were sampled during a rapid-assessment survey for introduced marine species in Puget Sound (Cohen et al. 1998).

Notes:

^a ITS alleles only. This marker did not distinguish *M. galloprovincialis* from the introduced Atlantic *M. edulis*, so samples listed here under *M. galloprovincialis* may have included both.

^b Mussels in present study selected for large size (all 3–10 cm shell length).

^c Mussels in Brooks (1991) selected for *M. galloprovincialis*-type morphologies.

^d In Anderson et al. (2002), hybrids were not distinguished from individuals with only *M. galloprovincialis* alleles.

^e *Mpi* alleles only.

been reported from Washington (Suchanek et al. 1997), and further sampling is warranted to determine whether *M. galloprovincialis* is invading intertidal as well as subtidal habitats.

Oregon and Northern California

On the Oregon coast, *M. galloprovincialis* alleles have been reported only from Yaquina and Coos Bays (see Table 1). Surveys in northern California (north of Cape Mendocino) repeatedly identify *M. galloprovincialis* alleles in Crescent City and Humboldt Bay (see Table 1). The central and southern California distribution of *M. galloprovincialis* is summarized elsewhere (McDonald & Koehn 1988, McDonald et al. 1991, Sarver & Foltz 1993, Suchanek et al. 1997).

Allele Frequencies

For a subset of sites in three Northeast Pacific regions (those sites at which *M. galloprovincialis* alleles were reported, and genetic markers distinguished heterozygotes from homozygotes), mean genotype frequencies were calculated (Table 2). In each region the observed frequencies differed significantly from Hardy-Weinberg equilibrium in goodness-of-fit tests using the total number of each genotype (see Table 2). These departures from equilibrium reflect an under-representation of *M. galloprovincialis* alleles, which is consistent both with the early stages of an invader's spread into a native population and with more general observations

of heterozygote deficiency in *Mytilus* populations (Raymond et al. 1997).

Invasion Pathways

It seems likely that *M. galloprovincialis* has been introduced to the Northeast Pacific through both aquaculture and shipping or boating. Most commercial *M. galloprovincialis* seed in the region is currently supplied by a single farm in Washington, which originally obtained its stock from California in the 1980s (G. King, Taylor United Shellfish, pers. comm.). These mussels were initially imported because they seemed to be resistant to bivalve disseminated-hemic neoplasia, a disease of unknown pathogenic agent that affects native *M. trossulus* particularly in culture (Brooks & Elston 1989a, Brooks & Elston 1989b). At the time of import, the genetic identity of the disease-resistant Californian mussels was not recognized (G. King, pers. comm.). The introduction date of *M. galloprovincialis* to California is unknown, but it has been suggested that historical records of a *Mytilus* invasion in southern California (Burch 1943–1958, Smith 1944, Coe 1945, 1946) reflect the arrival of *M. galloprovincialis* (Carlton 1979, Geller 1999). Aquaculture farms currently serve as localized sources of reproductively mature *M. galloprovincialis* whose larvae presumably disperse as far as currents permit. Additional dispersal within the region may occur from wild populations and via adult mussels transported on boat hulls.

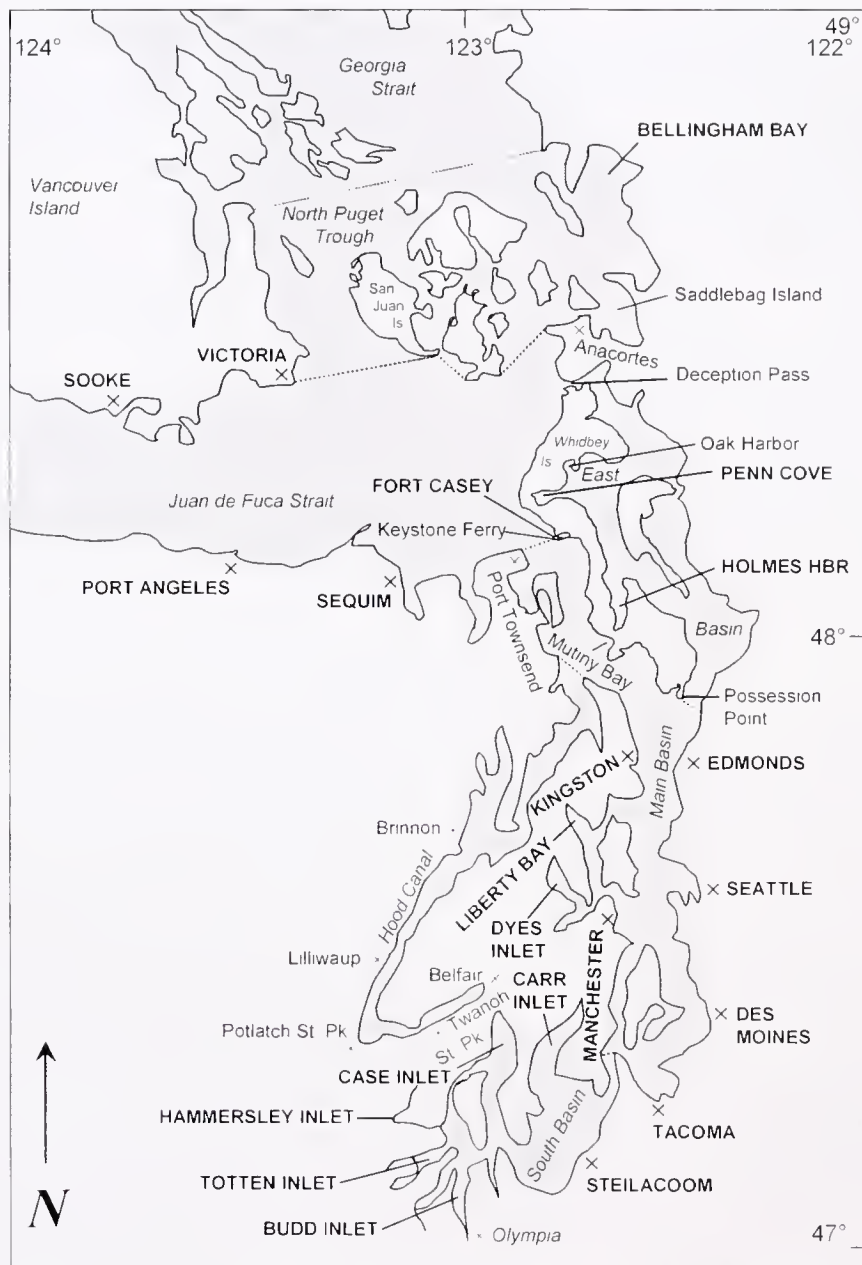

Figure 2. *Mytilus* spp. sampling sites in Puget Sound and Puget Trough, Washington. Sites where *M. galloprovincialis* genes were detected indicated in bold capitals. Sites where only *M. trossulus* genes were detected indicated in regular type. Landmarks indicated in italics. For details see Table 1.

Ship ballast water and ship and boat hulls may also provide a continual supply of organisms, including *M. galloprovincialis*, to Pacific Northwest waters (Carlton & Geller 1993, Geller et al. 1994, Suchanek et al. 1997). Shipping to the region comes primarily from Asia, where *M. galloprovincialis* is also introduced (Wilkins et al. 1983, Lee & Morton 1985, Inoue et al. 1995, Inoue et al. 1997, Suchanek et al. 1997, Wonham & Carlton 2004). This pathway may be particularly relevant to *M. galloprovincialis* populations along the Strait of Juan de Fuca, where Vancouver-bound vessels may deballast (Larson et al. 2003, Levings et al. 2004).

Within the northeast Pacific, no study to date has explicitly been designed to assess the spatial spread of mussels from aquaculture facilities, ports, or marinas. Detailed genetic investigation of possible source populations (i.e., Japan, California, and the

Mediterranean) may shed light on the likeliest invasion pathways for *M. galloprovincialis* to the region (Rawson & Hilbish 1995a, Sanjuan et al. 1997, Quesada et al. 1998). Within the region, sampling a range of mussel sizes and habitats (i.e., intertidal and subtidal; rock and floats) at increasing distances from farms, ports, and marinas could provide a clearer picture of the role of these potential *M. galloprovincialis* sources. Because the species is now widespread, more ecologically interesting questions concern its success and impacts as an invader (e.g., Hockey & Van Erkom Schurink 1992, Geller 1999, Gilg & Hilbish 2000, Secor et al. 2001).

The combined results reported here identify a major zone of sympatry and hybridization between *M. galloprovincialis* and *M. trossulus* in Washington waters, in addition to the well-recognized

TABLE 2.

Mean (± 1 SD) for homozygote and heterozygote *Mytilus* allele frequencies in 3 regions of the northeast Pacific from Table 1 (number of sites per region in parentheses). Allele frequencies in all 3 regions for Mg, homozygous *M. galloprovincialis*, Mt, homozygous *M. trossulus*, and Mg \times Mt, heterozygous hybrids, are significantly different from Hardy-Weinberg equilibrium at $p < 0.0001$, based on contingency table tests using the number of mussels of each genotype.

Site	Mg	Mg \times Mt	Mt	χ^2
Puget Sound (11)	0.18 (0.23)	0.24 (0.20)	0.63 (0.30)	228.9
Strait of Juan de Fuca (8)	0.06 (0.09)	0.20 (0.34)	0.74 (0.34)	136.5
Oregon & California (7)	0.15 (0.32)	0.04 (0.04)	0.81 (0.34)	495.3

California zone (McDonald & Koehn 1988, McDonald et al. 1991, Sarver & Foltz 1993, Suchanek et al. 1997). The apparent absence of *M. galloprovincialis* genes between Yaquina Bay, Oregon, and Cape Flattery, Washington, may reflect the absence of mussel culture and major shipping ports along this stretch of coastline. On

the other hand, given coastal currents and shipping traffic (Levings et al. 1998, Larson et al. 2003), and the associated potential for larval release and dispersal, it would not be surprising if further sampling revealed that the Washington and California zones comprised a larger *Mytilus*-complex hybrid swarm extending along the North American Pacific coast.

ACKNOWLEDGMENTS

Many thanks to J. Mitton and B. Kreiser at the University of Colorado, Boulder, and S. Edwards at the University of Washington, Seattle, for making laboratory space, equipment, and reference samples available. K. Ward provided expert laboratory assistance, and K. Brooks and two anonymous reviewers provided valuable comments. G. King and Taylor Shellfish Inc. generously made mussel samples available. This work was supported by Graduate Research Fellowship NA77OR0250, Estuarine Reserves Division, Office of Ocean and Coastal Management, National Ocean Service, National Oceanic and Atmospheric Administration (Padilla Bay National Estuarine Research Reserve). Access to Tatoosh Island was permitted by the Makah Tribal Council.

ABSTRACT This study evaluates the density, shell-size, and growth of the intertidal snail, *Calyptrea spirata* (Forbes 1852), in the beach of Teopa of Bahía Chamela, Jalisco, located in the tropical Mexican Pacific. The snail is one of the most important resources from the rocky shores of the region. Gastropod density and the size of the shell (maximum diameter and height) were estimated in the upper and lower intertidal zones and in wave-exposed and wave-protected areas of the beach on December 1999. Results showed that density is lower in the upper intertidal zone and increases in the lower intertidal zone (ANOVA, $P < 0.05$). The species was not registered in the supralittoral zone, while in the infralittoral zone it was observed to a depth of 3 m. There was no difference in the size of the shell between snails from the upper and lower intertidal zones (ANOVA, $P = 0.30$), although bigger shells (maximum diameter = 5.0 cm) were more frequently observed in the lower zone. Shell diameter was bigger in the exposed than in the sheltered areas of the beach (ANOVA, $P < 0.05$). The growth rate of snails smaller than 3 cm was higher (0.268 cm/month) than in bigger snails (0.077 cm/month) (ANOVA, $P = 0.037$). The ANCOVA test indicated that the least squares regressions of maximum diameter versus height of the shell correspond to differentiated morphologic responses to the wave intensity effect but no difference in these associations was detected in response to shore height.

KEY WORDS: density, shell-size, *Calyptrea spirata*, growth, Mexican Pacific

INTRODUCTION

It has been shown that wave intensity plays a major role in determining the abundance and vertical distribution of organisms living in the intertidal zone (Lewis 1964). In the Pacific shores, wave action intensity is particularly important because the extensive continuous surface area of this ocean makes longer and more intense waves relative to other oceans of the world (Ricketts et al. 1997). The rocky intertidal environment of the tropical Mexican Pacific includes a great variety of mollusks, gastropods being the most abundant and diverse. Many high energy rocky shores of this region are characterized by a dynamic topographic structure with a steep environmental gradient over short distances across the intertidal zone. Thus, the tidal regimen determines temperature, desiccation, and submersion time gradients, those that influence the organisms that inhabit intertidal shores (Levinton 1984). All these factors together with the biologic factors such as density or predation define the abundance and the zonation patterns of gastropod populations.

Differences in the size of the shell and growth of gastropods have been related to several physical conditions of the habitat including wave intensity (Brown & Quinn 1988, Denny 1994, De Wolf et al. 1999, Giraldo-Lopez & Gómez-Schouben 1999) and shore height (Vermeij 1972, Hobday 1995, Giraldo et al. 2002, Tanaka et al. 2002). Furthermore, density is considered responsible for intraspecific differences in shell size (Giraldo et al. 2002) and individual growth rate variability of gastropods (Haven 1973, Black 1977, Underwood 1978, Williamson and Kendall 1981).

The growth of mollusks have been traditionally estimated through the use of direct methods based on measurements of the size of the shell of individuals at different intervals of time (Gómez-Marquez 1994). The mark-recapture method is reliable to

estimate mollusk growth (Hughes & Roberts 1980, Phillips 1981, Fletcher 1984, Chow 1987, Katoh 1989, Bowling 1994, Takada 1995, Iijima 2001). In the Mexican Pacific, differences in the growth rate of the wavy turban snail, *Astrea undosa*, have been related to wave intensity (Cupul-Magaña & Torres-Moye 1996, Gluyas-Millán et al. 1999). Other studies describe variations in the size of the shell among populations living in areas with different wave exposition. In populations of the rocky intertidal snail *Thais* sp. from Baja California, the shell is shorter and heavier in exposed beaches and longer and slender in protected beaches (Kitching 1976). Similarly, the shell of the limpet *Siphonaria gigas* is wider when living in more wave exposed rocky beaches (Giraldo-López & Gómez-Schouben 1999), and the size of the chiton *Katharina tunicata* from northern California may be smaller in areas with stronger wave action (Stebbins 1988).

In the coast of Jalisco, México, there are few studies on growth and shell size of snails. Probably, the purple snail *Plicopurpura pansa* is the only species studied so far (Ríos-Jara et al. 1994, Michel-Morfin et al. 2002). One of the most important potential resources from the rocky shores of Jalisco is the so-called "gorrito" (small cap) snail *Calyptrea spirata* (Forbes 1852). The snail is easily distinguished for its conical limpet-like shell with large, coarsely ribbed, whitish or grayish outside, dark brown within without operculum. Its distribution ranges from Mazatlán to the Gulf of Tehuantepec, México (Keen 1971) and the Gulf of California (Morris 1966). In the coast of Jalisco, the species has been registered in the beaches of El Tamarindo, La Calechosa, Los Angeles (González-Villarreal 1977); Yelapa (Fonseca Madrigal 1998); Bahía Tenacatita (Hernández 1998), and in Bahía Cuastecomate (Esqueda et al. 2000). The muscular foot of *C. spirata* is most esteemed by fishermen who used it for food. The species has also a cultural traditional value in the region. It was used as a burial offering in pre Hispanic funerals recovered in the archaeological site of Salagua, Colima, dated between 900–1530 years B.C.

(Fieldman 1968). Recently, local populations have been diminished and in some beaches the species has disappeared, probably because of the intense fishing and deficient management activities. Although the taxonomic composition and abundance of rocky intertidal mollusk communities from the coast of Jalisco is well known, only a few studies focus on certain species, particularly on the population ecology of *Plicopurpura patula pansa*, a commercially important rocky intertidal snail (see Ríos-Jara et al. 1994, 2001, Pérez Peña & Ríos-Jara 1998, Esqueda et al. 2000 for a list of this research).

There are no previous studies on the population ecology of *C. spirata*. Therefore, the major objective of this study is to evaluate the abundance, vertical distribution, size, and growth of this species in Bahía Chamela, Jalisco, in the tropical Mexican Pacific. The study examines a population located in the beach of Teopa, in the southern part of the bay, which is well represented in terms of abundance, distribution, and size of the organisms. The size of the shell and the rate of growth were estimated in the upper and lower intertidal levels and at two different wave exposition conditions. This study provides basic knowledge concerning the factors that affect the growth and development of the species, which may be used to suggest future recommendations needed for the sustainable harvesting of the snail.

MATERIALS AND METHODS

Study Site

Chamela Bay is located in the central portion of Jalisco, México. The bay spreads 23.3 by 3 km between Punta Rivas and Punta Farallón (19°34'50"N to 19°23'20"N, 105°07'30"W to 105°01'40"W) and has a surface area of approximately 6,690 hectares. The region has warm-wet climate with the rainy season occurring mostly during the summer. Annual temperature ranges from 32.3°C in September to 20.6°C in January (mean = 25.2°C). Cumulative monthly precipitation ranges between 587.5 and 967.3 mm. September records the highest precipitation values with 301.7 mm and February the lowest with 1.6 mm (García 1973). There is a mixed tidal cycle with two unequal high and two unequal low tides each day.

The shoreline of the bay is composed of sandy and rocky beaches. The rocky beaches usually have solid blocks sometimes mixed with fixed or loose boulders and pebbles. The rocky beach of Teopa (19°23'33"N, 105°01'24"W) is located in the southern portion of the bay. The topography of the beach is very irregular with steep and smooth surfaces and heterogeneous rock platforms with water retaining cracks, crevices, and tidal pools. This irregular profile (slope = 60° to 90°) has many habitats with different degrees of exposure to wave action from sheltered to very exposed conditions through the intertidal zone. This beach was chosen because the population of *Calyptraea spirata* is well represented in terms of abundance, distribution, and size of the organisms. Preliminary observations were necessary to characterize the zonation of conspicuous species in the intertidal where *C. spirata* lives. Intertidal levels were determined using sessile forms, particularly macroalgae, crustaceans, and mollusks.

Methods

The beach of Teopa has a narrow intertidal zone (3–5 m). Two different levels were determined (upper and lower intertidal) for the study of gastropod density, shell size, and growth. At the same

time, 2 areas of the beach with different degrees of exposure to wave action were chosen: (1) a more sheltered part of the beach with relatively less wave intensity, and (2) a very exposed surf sweeping area with strong wave action. Sample size was estimated previously according to the cumulative means technique (Elliott 1977). For this technique, the cumulative mean density of snails was plotted as a function of the cumulative number of replicate samples or the cumulative area sampled. As the number of samples increased, the fluctuation of the mean decreased. The number of replicates was considered sufficiently large when such fluctuations were so slight that the cumulative mean became insensitive to variations in the data.

Density and size structure of the population found within the upper and lower intertidal zones and two wave exposure conditions (exposed and protected) were estimated during low tides in December 1999. The plot method was used for density estimations (Brower & Zar 1977). Line transects of 30 m and square plots (quadrats) of 0.25 m² were used. The procedure involved placing a series of 30 quadrats along each transect line, 15 on each side. The line was marked and numbered every 50 cm (60 numbers on each side) and a table of random numbers was used to choose the position of the quadrats along the transect. The number and size of snails found within each quadrat were estimated. The optimal sample size (25–30 quadrats) suggested by the cumulative means technique was used. A two-way ANOVA ($P < 0.05$) was used to determine whether the mean density (ind./m²) differed between intertidal zones and among the two wave intensity conditions. A posthoc test (Dunnett) was used to contrast mean densities estimated in the upper and lower intertidal zones and the protected and exposed areas.

The snails were measured to nearest 0.1 mm with a hand vernier caliper (maximum diameter and height of the shell). Maximum diameter values were used to make histograms of the size frequency distributions. Bimodality was tested by applying a 5% level of significance hypothesis test (Reschenhofer 2001). Differences in the size of the shell related to tidal level and wave exposure conditions were tested using a two-way ANOVA ($P < 0.05$). The normality and the homocedasticity of data (Bartlett's test) was examined, and the logarithmic transformation ($\log X + 1$) was performed when necessary (Zar 1999). If these conditions were not fulfilled, the non parametric mean comparison test of Kruskal-Wallis was used. The relationship between maximum diameter and height of the shell of individuals from different tidal levels and wave exposure conditions was described with least-squared regressions (Statistica Program SYNTAX 0.5 for Windows). The resulting equations were contrasted using an ANCOVA analysis (SPSS and SigmaStat Programs).

The growth rate was estimated during monthly samplings from October 1999 to May 2000 at the same areas and intertidal levels of the beach of Teopa where gastropod density and shell-size were studied. During the first sampling event, the shells of 300 snails from the upper and lower intertidal levels were measured (maximum diameter of the shell). Each individual was marked using plasticized epoxy glue (Plastiloca) and labels with printed progressive numbers. The labels were then coated with transparent instant nail varnish to preserve the numbers. All snails were released to their original position. The following months, marked individuals were measured and the numbered labels renewed when necessary. Increments in the size of the shell were documented and expressed in cm/week. New shells were labeled when the number of marked individuals decreased, so the total number was always similar to

the original. Sometimes, the somehow lost or not found snails were found again in later samplings. Individual growth rates (G) of the recaptured snails were estimated using the equation (Iijima 2001):

$$G = \Delta X / X (30/T)$$

where T is the time (month) from the last release to recapture, X the maximum diameter of the shell at the last release, ΔX the increment in maximum diameter during the period T .

For comparative purposes, snails were divided in 2 groups: Group 1, included snails smaller than 3 cm of maximum diameter and Group 2, those snails of more than 3 cm of maximum diameter. A one-way ANOVA ($P < 0.05$) was performed to compare the growth rate of both groups of snails.

RESULTS

Mean density of *Calyptraea spirata*, increases from the upper to the lower level of the intertidal zone (Fig. 1). The density was lower in the upper intertidal zone compared with the lower intertidal zone of both the protected and the exposed areas (ANOVA, Dunnett test, $P < 0.05$). The species was not registered in the supralittoral zone in any area of the beach, whereas in the infralittoral zone it was observed (but not sampled for density estimations) to a depth of 3 m. Snails in the infralittoral were also attached to rocky substrata, defining a wide vertical distribution from the upper intertidal to the shallow infralittoral zones. Within the same shore height (upper or lower intertidal), no significant variation in gastropod density was detected between the sheltered and the exposed parts of the beach (ANOVA, $P > 0.05$).

Histograms of the size frequency distributions of individuals show at least one mode in upper intertidal zone of both the protected and the exposed areas of the beach (Fig. 2). In the protected area, the mode extends along all size ranges of the histogram, from 0.4–5.0 cm: in the exposed area, the mode includes the ranges of 1.0–4.5 cm. According to the hypothesis test ($P < 0.05$), histograms of individuals from the lower intertidal are bimodal. In the protected area, the modes occur in the size ranges of 1.0–1.5 and 3.1–3.5 cm of shell diameter; in the exposed area, the modes occur in the size ranges of 1.6–2.0 and 3.1–3.5 cm. During the study, the diameter of the shell ranged from 0.40 cm for the smallest individual to 5.0 cm for the largest individual measured. The mean diameter was found to be 2.86 ± 0.75 mm (\pm one standard deviation).

Figure 1. Mean density (ind/m² \pm one standard deviation) of *Calyptraea spirata* in the beach of Teopa, Jalisco (December, 1999). Estimated densities of two areas of the beach with different degrees of exposure to wave intensity (exposed and protected) at two intertidal zones are shown.

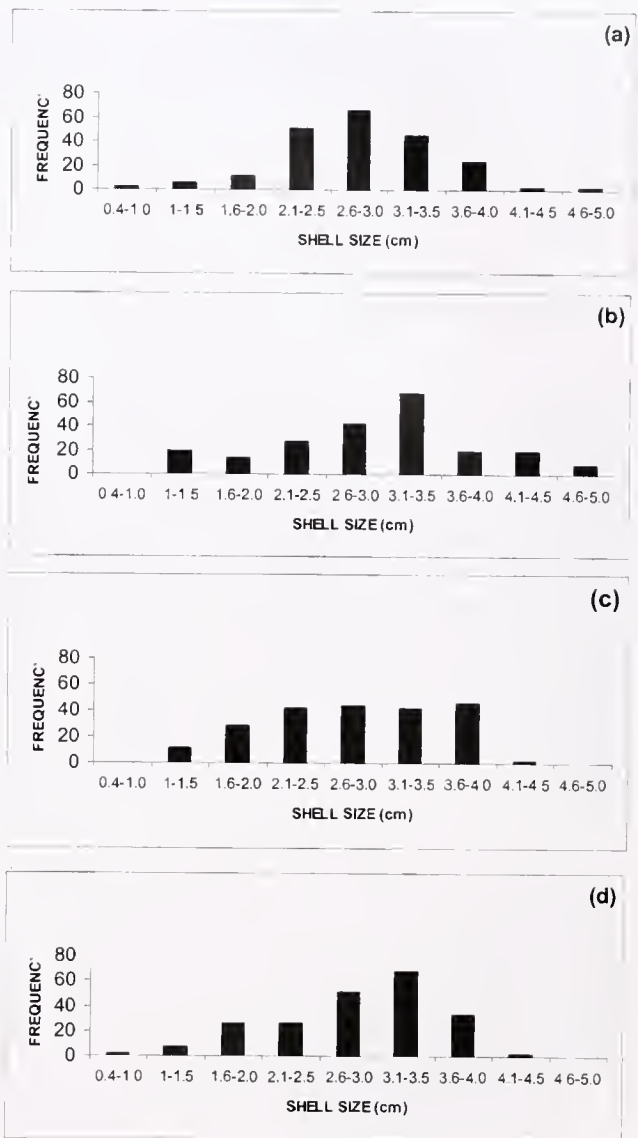

Figure 2. Histograms of the size frequency distributions of individuals at two intertidal zones with different degrees of exposure to wave intensity in the beach of Teopa, Jalisco (December, 1999). (a) Protected Upper intertidal; (b) Protected Lower intertidal; (c) Exposed Upper intertidal; (d) Exposed Lower intertidal.

tion). The most common repeated value of diameter was 3.1 cm (by 3.5%), 3.0 cm (by 2.8%), and 2.8 cm (by 2.5%).

The homoscedasticity condition was not fulfilled by shell diameter even with logarithmic transformation (Bartlett test, $P < 0.01$), so the non parametric test of Kruskal-Wallis was used to detect differences in shell size. Although the biggest individuals were always found in the lower intertidal zone, no significant difference in shell diameter between snails from the upper and lower intertidal zones was detected (ANOVA, $P > 0.30$) (Table 1). However, the shell-diameter of *C. spirata* was bigger at the most wave-exposed areas compared with the wave-protected areas of the beach (ANOVA, $P < 0.05$).

Individual growth rates did not varied greatly between individuals from different shore heights and wave exposure conditions (Table 2). The growth rates were significantly different in only 2

TABLE 1.

Mean size of the shell (maximum diameter and height, cm \pm one standard deviation) of *Calyptraea spirata* at 2 intertidal zones of the beach of Teopa, Jalisco with different degrees of exposure to wave intensity (exposed and protected) (December, 1999).

Intertidal Zone		n	Exposed	n	Protected	Mean
Upper	Maximum diameter	216	2.79 \pm 0.74	212	2.83 \pm 0.67	2.81 \pm 0.70
	Height	216	1.85 \pm 0.57	212	2.02 \pm 0.47	1.93 \pm 0.53
Lower	Maximum diameter	218	2.85 \pm 0.70	220	2.97 \pm 0.87	2.91 \pm 0.79
	Height	218	1.85 \pm 0.51	220	1.92 \pm 0.68	1.91 \pm 0.60
Mean	Maximum diameter	434	2.82 \pm 0.72	432	2.90 \pm 0.78	2.86 \pm 0.75
	Height	434	1.85 \pm 0.54	432	1.96 \pm 0.59	1.91 \pm 0.57

situations: (1) when comparing all snails of group 1 versus group 2, the growth rate of individuals smaller than 3 cm (Group 1) was significantly higher than the growth rate of larger individuals (Group 2) (ANOVA, $P = 0.037$); and (2) in the case of snails of group 2 inhabiting the upper intertidal, results indicated that there is a significant difference in the growth rate between exposed and protected conditions (ANOVA, $P = 0.018$).

The least squares regressions of maximum diameter versus height of the shell were examined by shore height and by wave exposure conditions (Fig. 3). All associations were significant ($P < 0.05$). The ANCOVA test indicated that these associations correspond to differentiated morphologic responses to the wave intensity effect ($P < 0.05$), whereas regressions calculated in the two different intertidal zones were not significantly different ($P > 0.05$).

DISCUSSION

The intertidal area of Teopa beach shows important environmental differences that explain the vertical gastropod variation found in this study. Several biotic factors should have an important role in the explanation of the observed density, shell size, and growth rate variations; including the human impact on gastropod populations; and the natural predation and competition.

The harvesting pressure by humans was considered responsible for the small size of *Monodonta labio*, an edible rocky intertidal

snail in Amakusa, Japan (Iijima 2001). Furthermore, the growth rate in Amakusa was slower than in other localities possibly because the selective collection of large *M. labio* by human. In Chamele Bay, fishermen use different mollusk species (limpets, snails, mussels, chitons and octopuses) from the rocky shores. *Calyptraea spirata* is preferred over all other intertidal and shallow subtidal gastropods. The last report of the capture of the snail from the government's Fishery Office in Puerto Vallarta, Jalisco, indicate a very small volume of 106 Kg in 1995 (Esquivel & Plascencia 1999). In recent years, the capture of the snail is no longer reported by the Mexican government, probably because of a decrease of the previously exploited populations and the absence of adequate mechanisms to obtain accurate information on the harvesting of the snail. Nowadays, the species is found abundantly only in a few beaches of Jalisco that may be considered as relics, because access is difficult for fishermen. Although access to Teopa beach is restricted mainly because the entrance walkways go across private properties, the beach is regularly visited by local people. The snail is mostly harvested from the upper intertidal zone where it is easier to reach and there are less hazardous conditions. The strong waves and heavy surf of the lower intertidal prevent fishermen from collecting the snails even in the sheltered areas of the beach. On the other hand, natural predation also affects gastropod density and shell-size in tropical intertidal habitats (Palmer 1979, Garrity & Levings 1981, Menge & Lubchenco 1981). Shell-breaking preda-

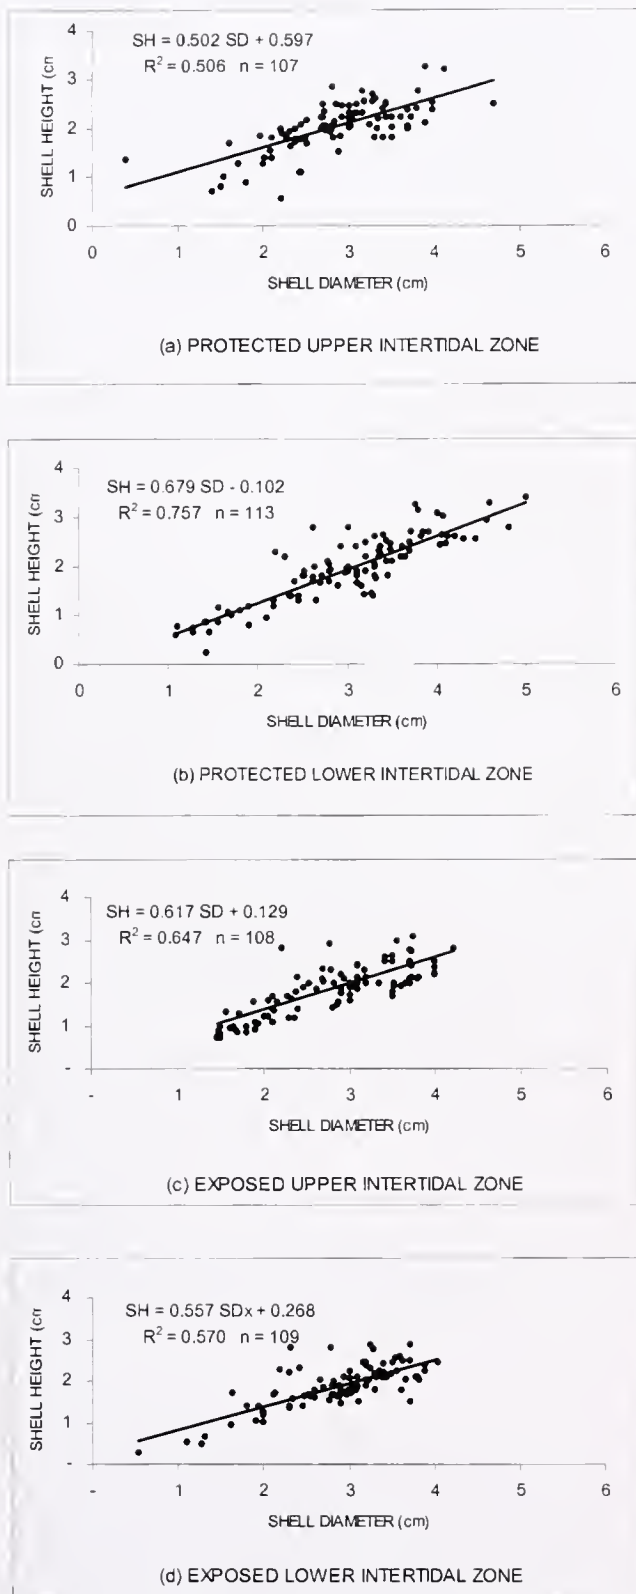

Figure 3. Fitted linear regressions of shell diameter (SD) vs shell height (SH) for *Calyptraea spirata* at two intertidal zones with different degrees of exposure to wave intensity in the beach of Teopa, Jalisco (December, 1999). (a) Protected Upper intertidal; (b) Protected lower intertidal; (c) Exposed Upper intertidal; (d) Exposed Lower intertidal.

tors of gastropods include fishes and crustaceans (Vermeij 1978, Bertness & Cunningham 1981). In the rocky shores of Jalisco, several mammals and sea birds have been observed as predators of snails (Ríos-Jara et al. 1994). During the high tide periods, predation by fishes and crustaceans may be more intense while during the low tide periods, predation by mammals and birds is more important. Consequently, the predation intensity should be influenced by intertidal shore height and it is probably related to the vertical variation in density and shell-size found for *C. spirata* in Teopa beach.

The interspecific and intraspecific competition for food has a considerable effect on gastropod density (Underwood 1979, Creese & Underwood 1982, Underwood & Denley 1984) and growth rates (Paine 1969) in rocky intertidal habitats. Food resources have been also considered as responsible for differences in growth rates in intertidal gastropods (Takada 1995). The members of the Family Calyptraeidae are filter-feeding gastropods that consume microplankton and suspended organic matter from water (Ruppert & Barnes 1996). Field observations indicate that *C. spirata* may have this feeding strategy, because snails were seen rising the shell from the substratum only during the upcoming and lowering tides. Little or no movements of marked individuals were detected during the study, indicating that snails do not need to move much to filter food items from the surrounding waters. Therefore, gastropod density difference through the intertidal zones may be related to the tidal regimen, which determines an emergence and submersion time gradient, and influence the food availability for gastropods.

Previous studies have suggested that the density of intertidal gastropods is affected by abiotic factors such as wave action, temperature, and desiccation (Atkinson & Newbury 1984, Raffaelli & Hawkins 1996, Gluyas-Millán et al. 1999, Tanaka et al. 2002). Differences in shell-size and growth rate have been explained in response to the effects of wave exposure and shore height (Crothers 1992, Giraldo et al. 2002). In the case of *C. spirata*, the growth rate of individuals smaller than 3 cm was significantly higher than the growth rate of larger individuals. Similarly, Williamson and Kendall (1981) found that the growth rate of the rocky intertidal snail *Monodonta lineata* from the coast of England decreases with the size of the individuals. The same situation was later found for *M. labio* in Japan (Iijima 2001). Differences in the growth rate between smaller and bigger individuals may be related to the reproductive effort of adults. Thus, sexual maturity may imply more energy used for reproduction instead of shell growth.

The tropical intertidal zone experiences continuous severe physical conditions during daytime exposures to sun and air. Substratum temperatures in tropical rocky shores may be extreme in sunny weather, and lethal stress levels can be reached on open surfaces on a clear day (Giraldo et al. 2002). Although, *C. spirata* live on the exposed areas of the rocks where the wave action and the sunlight are important restrictive factors (Santés-Alvarez & Hernández 1983, Williams & Morritt 1995). Adaptations to the exposed areas of *C. spirata* include the wide cap-shaped hydrodynamic shells that diminish the effect of direct wave action and tidal currents; a wide shell aperture, and an extensive foot that gives a stronger attachment to the rocky substratum. The rigor of desiccation and extreme temperatures in the rocky intertidal increases according to a gradient from low to high shore heights. Therefore, those gastropod species living through the intertidal zone may have density variations related to this gradient. *Calyp-*

traea spirata has a wide vertical distribution, but the number of snails increases from the upper to the lower level of the intertidal zone. Other studies have shown variable vertical distribution patterns in the rocky beaches of Jalisco; many gastropod species also increase their numbers from the supralittoral to the lower tidal zones whereas the opposite occurs in other species (Esqueda et al. 2000, Ríos-Jara et al. 2001). Marked differences in vertical distribution of species or their absence in some intertidal levels closely relate to the transient nature of the littoral environment, which changes from nearly terrestrial to completely marine conditions. Environmental cues that govern distribution of these species were not evaluated, but we predict that they respond to features of the habitat, which are very variable across the shore.

Several other factors (e.g., mating, feeding, and interspecific relationships) may be important regulating factors. Vertical distribution of many gastropod species closely relate to the presence of other invertebrates in the rocky beaches of California (Sledner 1981) and Baja California (Ríos-Jara 1983). Other species are similarly associated with the mats of macroalgae and the aggregations of mussels (*Brachidontes* sp. and *Chloromytilus* sp.) in the coast of Jalisco (Esqueda et al. 2000). *Calyptrea spirata* form aggregations of individuals regularly distributed one next to the other. The snails have a rich epibiota growing on their shells. This epibiota consist mostly of algae together with acorn (balanomorpha) and goose (lepadomorpha) barnacles, polychaetes, amphipods, bivalves, limpets, and bryozoans that moisten and shade the snails and incidentally give them protection against the sun and the predators. The aggregations of *C. spirata* are therefore protected from high temperatures and desiccation, the two most restrictive physical factors throughout the long periods of exposure during the low tides in the rocky intertidal.

There is strong evidence that wave intensity is an important agent of shell-size variation in intertidal gastropods. Recently, Gómez et al. (2001) reported the variation in shell-thickness of the limpet *Notoacmea biradiata* due to wave intensity, being the shell thicker in exposed rocky shores. The shell size of *C. spirata* was bigger at the most wave-exposed areas compared with the wave-protected areas of the beach. The same condition has been reported for the turbinid snail *Astraea undosa* in 2 localities of Bahía Tortugas, Baja California Sur, México (Gluyas-Millán et al. 1999) and for the trochid snail *Monodonta labio* in the Pacific Coast of Central Japan (Iijima 2001). *Calyptrea spirata*, is a tenacious snail very well adapted to high wave energy habitats, particularly in the rocky intertidal and shallow subtidal zones of exposed coasts. Specimens are found in the most surf-beaten rocks (Keen 1971) where strong waves and currents are definite factors. The wide shell aperture and extensive foot gives to the organisms a better

attachment to the rocky substratum. The irregular margin of the shell adapts well to the irregular microtopography of the rocky substratum, so the water trapped inside during the low tide periods prevents from desiccation and high temperatures, giving oxygen supply for low metabolism. During the periods of low tide, when *C. spirata* is exposed to desiccation and strong variations in temperature, the snails remain strongly attached to the rocky substratum apparently retaining seawater in the cavity of the mantle. Water retention is an important mechanism to avoid an excessive increase in body temperature and allows minimal gas exchange during these periods of low activity and metabolism. Therefore, many intertidal gastropods species change the size of the shell in response to desiccation and temperature (Lowell 1984, Branch 1985). Vermeij (1973) reported a negative relationship between shell size and intertidal height. However, in this study, the shell size of *C. spirata* was not affected by its intertidal position; it is probable that desiccation and temperature do not sufficiently affect the gastropods so their shells do not express a morphologic response to these factors.

In conclusion, the results of this study suggest that the density of *C. spirata* was significantly different between intertidal zones, increasing from the upper to the lower areas of the beach of Teopa, Jalisco. However, there is no gastropod density difference between the sheltered and the exposed parts of the beach. On the other hand, the shell-size variation was associated with wave intensity, with bigger shells (greater shell diameter) being found in the most exposed areas of the beach compared with the protected areas. Although the bigger shells were found in the lower intertidal zone, shore height did not show a significant effect on the size of the shell for *C. spirata*. Individual growth rate of snails smaller than 3 cm of diameter was higher than the rate of larger individuals. The larger snails inhabiting the upper intertidal had significant differences in growth rate when comparing exposed to protected conditions. In contrast, the smaller snails, showed no difference in the growth rate related to wave exposure. Finally, shore height did not show a significant effect on growth rate, because individuals from the upper and lower intertidal zones have similar growth rates. Of many possible factors, shore height, wave intensity, and human impact might be at least partly responsible for these differences. This study, however, was conducted during one season only. Thus, more research is necessary to verify whether these patterns remain common over several seasons. Furthermore, the significance of other biotic factors such as gastropod density, natural predation, and competition should also be taken into consideration in future studies, together with physical factors, principally the desiccation and temperature gradients through the intertidal zone during the low tide periods.

SIZE SPECIFIC FECUNDITY OF RED ABALONE (*HALIOTIS RUFESCENS*): EVIDENCE FOR REPRODUCTIVE SENESENCE?

LAURA ROGERS-BENNETT,^{1,2,*} RICHARD F. DONDANVILLE³ AND JERRY KASHIWADA⁴

¹California Department of Fish and Game and ²U.C. Bodega Marine Laboratory, PO Box 247, Bodega Bay, CA 94923; ³5342 Winding View Trail, Santa Rosa, CA. 95404; ⁴CDFG, 19160 S. Harbor Dr., Fort Bragg, CA 95437

ABSTRACT The fecundity of wild red abalone, *Haliotis rufescens*, was examined during four reproductive seasons (2000–2003) in northern California. A broad size range of abalone were sampled ($n = 425$) from Van Damme State Park and the Point Arena area. Sexual maturity was defined as the presence of sperm or mature oocytes 170–190 μm in diameter, with a jelly coat, detached from the trabeculae in the gonad. Histologic examination revealed that abalone <50 mm in shell length had not yet sexually differentiated and that 50% of the females from 105–130 mm and the males 75–95 mm had mature gametes while all larger animals were mature. Fecundity, as measured by an estimate of the number of mature eggs per female (X), increased exponentially with increasing shell length (Y) until the peak at 215 mm in shell length after which mature egg number began to decline. The largest female 260 mm (10.24 inches) had >80% necrotic eggs. The data were fit to a non-linear Gaussian curve with 3 parameters;

$$(Y) = Ae^{-(X-\mu)^2 / 2\sigma^2}$$

the maximum productivity ($A = 2,850,000$ eggs y^{-1}), size at maximum productivity ($\mu = 215$ mm), and standard deviation ($\sigma = 38$ mm) of the distribution of maximum productivity versus size. We conclude that whereas large females in excess of 215 mm in shell length undergo some senescence (decline in egg production), these females could potentially contribute as much to reproduction as the mid-size (130–215 mm) females. This suggests that management strategies that protect large females such as marine protected areas or *de facto* reserves will help maintain egg production and that more work is needed to better understand the relationship between female size and egg necrosis.

KEY WORDS: abalone reproduction, *Haliotis rufescens*, size at maturity, necrotic eggs, molluscs, northern California

INTRODUCTION

A basic understanding of reproduction and other vital rates for red abalone, *Haliotis rufescens* (Swainson 1822), populations is necessary for both ecologic studies and fishery management of wild populations. Management strategies such as minimum legal sizes depend on reproduction occurring prior to the onset of fishing. Knowledge of size specific fecundity and size at maturity can be used in size-structured models to examine the population dynamics of wild stocks. Whether the largest oldest females contribute to reproduction, undergo partial or complete reproductive senescence has important implications for population dynamics and management.

Red abalone populations in northern California support an important recreational fishery. Unlike the southern abalone fishery, which was closed in 1996 following intensive fishing (Dugan & Davis 1993, Karpov et al. 2000), the northern fishery is very active with landings estimates ranging from 400,000 to 700,000 red abalone taken per year (CDFG unpubl data). This northern fishery is unique in several ways (1) the use of SCUBA and commercial fishing has been prohibited for more than 40 years; (2) there are few access points along the rugged coastline; and (3) there are long periods of rough ocean conditions. The fishery in the north with an estimated 40,000 fishers is also managed using a combination of a minimum size limit (178 mm), season closures (December to March and July), daily (3/day) and yearly bag limits (24/year), and closed areas. The fishery generates a yearly average of \$13.2 million (1985–1989) in tourism revenue to northern coastal communities (CDFG 1997). As with many fisheries, the recreational abalone fishery highly prizes large trophy animals.

Previous abalone reproduction studies have identified a number of important features associated with wild red abalone in northern California. First, there may be a difference in the size at maturity between males and females (Giorgi & DeMartini 1977); second, red abalone are capable of being highly fecund producing more than 12 million eggs (Giorgi & DeMartini 1977); and third, necrotic eggs have been found in mature females (Young & DeMartini 1970, Giorgi & DeMartini 1977). Laboratory conditioning (feeding kelp) has been shown to reduce the size at first maturity and increase estimates of fecundity by 260%, relative to wild abalone (Ault 1985). These results suggest that reproduction studies based on laboratory (or aquaculture) reared red abalone may not be relevant for wild populations. It is unknown whether the largest females have more necrotic eggs suggesting the possibility of reproductive senescence, as has been found in some other mollusks (Downing et al. 1993).

Red abalone fecundity and size at maturity was investigated for wild animals in northern California. Red abalone populations are centered along 480 km of rocky coastline dominated by bull kelp, *Nereocystis*, in Sonoma and Mendocino Counties north of San Francisco. Samples of red abalone were collected from Van Damme State Park ($n = 393$) over 4 years (2000–2003) and from the Point Arena Abalone Derby ($n = 32$) in 2000 and 2001. For each abalone, gonad volume was determined and samples of gonad tissue were prepared for histologic assessment of reproductive condition. Histologic evaluations were conducted to determine the maturation stage of the ovaries and testes. The potential fecundity of each female was estimated by multiplying estimated gonad volume by the mean number of mature eggs enumerated per slide excluding the necrotic eggs. We discuss the relationship between abalone size, and fecundity as well as reproductive senescence and it's implications for the ecology and management of red abalone populations in northern California.

MATERIALS AND METHODS

Collections

A total of 393 red abalone ranging in shell size from 29–224 mm were collected at Van Damme State Park, CA (lat. 39°16'08"N, long. 123°47'58"W) with 137 in April 2000, 71 in January 2001, 62 in February 2002, 123 in January 2003, and 8 in September 2003 (Fig. 1). Sublegal red abalone ranged in size from 29–224 mm in shell length from Van Damme State Park and 212–260 mm from the Point Arena Abalone Derby. Red abalone were collected using SCUBA from depths ranging between 5 and 15m.

The fecundity of the smallest animals (<150 mm) was examined using abalone collected in January and September 2003. The fecundity of the largest red abalone was examined by sampling at the annual Point Arena Derby where recreational fishers skin dive (no SCUBA) for the largest abalone from Sonoma or Mendocino County. The Derby was held August 5, 2000 ($n = 18$), and August 4, 2001 ($n = 14$). Data were not included from the Derby in August 2002, because only three abalone were entered. The Derby was not held in 2003.

Laboratory Dissection and Preparation

All animals were weighed and the length of the shell was measured then, the foot and organs were detached from the shell (shucked) and weighed. Sex was determined by visual examination of the gonad and later confirmed histologically. Mature female

gonad tissue appears dark green in color whereas the male gonad is tan. The length and width of the conical gonadal appendage, including the inner digestive gland core was measured. Slices were made half way down the appendage and the height and width of the gonad/digestive cone and the height and width of the inner core of the digestive gland were measured (Fig. 2). The digestive gland is dark brown in color. Gonad dimensions for animals <125 mm shell length were measured microscopically with an ocular micrometer. Gonad volume was estimated by assuming that the digestive gland and gonad were cone shaped. The volume of the inner digestive gland cone was subtracted from the total cone volume to yield the volume of the outer gonad cone as described by Tutschulte (1976), and Tutschulte and Connell (1985). The gonad index was defined as gonad volume *100/abalone body weight.

Samples of the gonad were taken for histologic preparation from the mid-section. All gonad samples were fixed in invertebrate Davidson's solution (a formalin based fixative) (Shaw & Battle 1957) for 24 hours, then transferred to 70% ethanol. Once in alcohol the tissues were processed for paraffin histology. Deparaffinized 5- μ m sections were stained with hematoxylin and eosin (Luna 1968), and mounted on slides for examination using light microscopy. Not all samples had enough gonad tissue to score and some abalone tissue sections were not quantifiable and so we report the histologic results from 86 abalone in April 2000, 62 from January 2001, 62 from February 2002 and 123 from 2003.

Classification of Oocytes

Three classes of oocytes were identified: immature, mature, and necrotic (degenerating) (Young & DeMartini 1970, Brickey 1979, Martin et al. 1983). Immature oocytes range from 5–60 μm in diameter, stain violet, and attach to trabeculae in the gonad. The larger immature oocytes, 40–60 μm diameter become pear shaped and have a distinct nucleus. Slightly larger oocytes, approaching mature size but still attached to trabeculae, were classified as immature. Mature oocytes were 170–190 μm diameter and approximately circular.

They have a speckled, densely granular appearance due to a combination of colorless lipid droplets, <6 μm diameter, set in a magenta-stained yolk groundmass. Lipid droplets comprise 30% to 50% of the oocyte volume. The nucleus is usually crescent shaped. The oocytes are surrounded by three extra-cellular layers: a 1- μm vitelline layer, a chorion about 10 μm thick, and the jelly coat 10–20 μm thick. Mature oocytes are detached from the trabeculae, free to be released at spawning.

Young and DeMartini (1970) and Giorgi and DeMartini (1977) first described necrotic oocytes that appear to be autolysing residual mature oocytes. The necrotic oocytes are approximately the same diameter as mature oocytes and are composed of irregular, textureless, orange eosinophilic masses up to 50- μm wide and set in a fine mesh of dark purple basophilic material. Numerous vacuoles up to 30- μm diameter connect to give the oocytes a spongy, mosaic appearance. In the early stage of necrosis the oocytes are the same size and shape as mature oocytes. In more advanced stages, the oocyte wall distorts and ultimately ruptures, dispersing the cell contents into the gonad.

Fecundity Estimates

In addition to the gonad volume the total number of mature eggs was determined for each abalone. Egg number was estimated by counting all the mature eggs in 4 microscope fields ($\times 200$), dividing by the volume of the 4 fields, and multiplying by the

gonad volume. The volume of a microscope field is equal to the area of the field times the thickness. The area was calculated using an ocular micrometer for field dimensions. Because a small mature oocyte section can be from an oocyte largely above or below the section plane, the thickness was defined as twice the average oocyte diameter. The average oocyte diameter was 176 μm , exclusive of the jelly layer. It was determined by measuring the diameter of 1000 of the largest, roundest oocytes in the sections, and by measuring fresh oocytes.

These methods were used to estimate the number of immature eggs in the smaller females, <125 mm and necrotic eggs in all size females. For abalone <76.6 mm all oocytes were counted. Due to the dramatic increase of the number of oocytes in abalone >76.6 mm, only larger oocytes, 40–60 μm were counted, because smaller oocytes were too numerous to count. Necrotic egg number was estimated by counting all the necrotic eggs in 4 microscope fields ($\times 200$), dividing by the volume of the 4 fields, and then multiplying by the gonad volume.

RESULTS

Size at Maturity

Abalone shell length was related to reproductive maturity (Fig. 3 and 4). The smallest female with mature oocytes capable of spawning was 106 mm long and weighed 170 g. The smallest animal that could be identified as a female with immature oocytes had a shell length of 50 mm, and a body weight of 15 g. Animals less than 50 mm did not have differentiated gonad tissue. There were 19 immature females ranging from 50–104 mm. Only 6 of 17 females between 106–126 mm had mature oocytes. All 48 females from 129–175 mm had mature oocytes.

Mature males were found at a smaller size than females. The smallest male with sperm was 75 mm and weighed 40 g. The smallest male with spermatocytes and testis structure was 64 mm, and weighed 30 g. Of eight males in the 75–91 mm size range four of them had sperm. All the males between 91–175 mm had sperm ($n = 63$) with three exceptions that were large males (collected April 2000) with well developed testis structure and spermatocytes.

cytes, but no observable sperm, suggesting they spawned prior to collection.

Size Specific Reproduction

Gonad volume increased with increasing shell size after 50 mm shell length for females and 64 mm for males. No gonad tissue was visible for abalone smaller than 50 mm in shell length using the microscope. Gonad tissue, or tissue destined to become gonad, appeared as a thin purplish membrane around the digestive gland for animals 50–75 mm. Gonad indexes and sex for all abalone <112 mm (and some abalone in the 114–126 mm size range) with these thin membrane-like gonads were determined from the histologic sections. Abalone >129 mm were measured macroscopically during dissection. These measurements revealed that females ranging in size from 50–75 mm had very thin sections of gonad (<50

μm) with few immature eggs averaging 801 immature eggs per female ($n = 3$). For example, within the three gonad cross sections of a 65-mm female; two sections had no oocytes; whereas the third had only three immature oocytes. Females greater than 75 mm in shell length had dramatically thicker gonad tissue layers (>250 μm) accompanied by a large increase in the numbers of immature eggs averaging 725,763 immature eggs for females 75–100 mm ($n = 8$).

Egg number increased rapidly until a shell length of 215 mm when mature egg number declined (Fig. 4). The relationship between shell length (X) and egg number (Y) can be modeled using a Gaussian curve of the form:

$$(Y) = Ae^{-(X-\mu)^2/2\sigma^2}$$

where A is defined as the maximum productivity, μ is the size at maximum productivity, and σ the standard deviation describes the

Figure 4. Graph of the relationship between mature egg number and adult female red abalone size ($n = 154$) from Van Damme and Point Arena in northern California modeled using a Gaussian curve. One female (233 mm length) was outside the 99.9% prediction interval with more than 11 million eggs and was excluded from the Gaussian curve fit.

width of the distribution of maximum productivity versus size. Females are subject to fishing pressures from 177 mm to 253 mm (± 1 SD) and this size class is potentially responsible for 68% of the total mature egg production whereas sublegal females will produce 32% of the egg production.

The smallest mature female (105 mm) had the fewest mature eggs ($\approx 2,400$) whereas the largest females had the most eggs (Table 1). Mature egg number increased from an average of 63,000 for females ranging in size from 90–120 mm to 2.5 million eggs per female from 178–220 mm and 3 million for the largest females >220 mm. The average number of mature eggs increased per gram of body weight from 330 for females from 90–120 mm in shell length to almost 2,500 eggs per gram of body weight for females 178–220 but declined to 2,000 eggs per gram of body weight for the largest size class >220 mm. In contrast to the small females with few oocytes, the small males (75 mm), had abundant sperm (Table 2).

Necrotic Eggs

The largest red abalone had high percentages of necrotic eggs (Table 3, Figs. 3 and 4). The largest red abalone in the collection (260 mm) from the sport derby had $>80\%$ necrotic eggs. The smaller abalone (80–120 mm) had the least number of necrotic eggs.

DISCUSSION

Abalone Size and Reproduction

Histologic examination of gonad tissues revealed that reproductive stage was related to shell length (see Table 3, Fig. 3). Red abalone became sexually differentiated at approximately 50 mm when primary oocytes or spermatocytes (or sperm) are first observed in the gonad tissue. In females >75 mm in shell length, there was a dramatic increase in the thickness of the ovary tissue accompanied by an exponential increase in the number of primary oocytes (see Table 3). The smallest female with mature oocytes was 105 mm, although it was not until a shell size of 130 mm that 100% of the females had mature eggs and the number of mature eggs increased dramatically. Egg number increased to a peak at an abalone shell length of 215 mm, followed by a decrease in mature

egg number as abalone size increased due to an increase in the number of necrotic eggs (Table 3 and Fig. 4). The peak number of eggs estimated from the Gaussian curve was 2,850,000 eggs, although many individuals had more eggs than the peak of the curve and one individual had in excess of 11 million eggs. Females from this same site, however, have been estimated to produce up to 23 million eggs (Rogers-Bennett et al. MS in prep). The largest females had the highest percentages (80–90%) of necrotic eggs (see Table 3 and Fig. 4).

Size at First Maturity

Other studies examining the size at first reproduction support our results. Giorgi and DeMartini (1977) also found that small female abalone 40–50 mm in length had immature oocytes (see Table 3, Fig. 3), however different criteria were used to define maturity. We define maturity as requiring the presence of mature oocytes. Mature oocytes can be distinguished from immature (<50 μ m in diameter) based on egg size (180 μ m in diameter), having both stained yolk and lipid droplets and being detached from the trabeculae (stalk), ready to be spawned (see Fig. 3). Samples collected in this study in January and September 2003 showed that the smaller abalone 50–100 mm did not have mature oocytes. Giorgi and DeMartini (1977) also found that abalone <132 mm collected in June and July only had small (<50 μ m) immature eggs. Ault (1985) collected wild red abalone and found that only female red abalone >110 and males >60 mm spawned successfully after artificial induction (using hydrogen peroxide) further supporting our conclusions.

There was a large gap in sizes between immature and mature males and females (Tables 1 and 2). Females with immature oocytes were 50 mm in shell length and those with mature oocytes were 130 mm. This suggests two alternative hypotheses: either the eggs from smaller females mature at a different time of year, which we missed with our sampling dates (January and September 2003) or it may take a few years before ovaries mature. Eggs from female frogs, *Rana temporaria*, take 3 years to mature (Grant 1953). A Gaussian growth curve has been used to estimate that it would take 3–4 years for females in northern California to grow from 50 mm to maturity at 105 mm and 1–2 years for males to mature from 50 to 75 mm (Rogers-Bennett et al. MS in review).

We found a significant difference in the size at maturity between the sexes with females maturing at a larger size than males, as was found in the southern California (Tutschulte 1976, Tutschulte & Connell 1985). Wild abalones in southern California have also been found to mature at large sizes. Tutschulte (1976) found that 4 of 19 pink abalone in the size ranges from 59–119 mm had mature oocytes, and that green abalone mature at 101 mm. More studies however, are needed on the time and food resources required for maturation of gametes in wild populations.

Oceanographic conditions are known to influence abalone reproduction and successful recruitment (Shepherd et al. 1998). For example, El Niños are associated with decreased dissolved nitrogen levels, poor kelp growth (Tegner et al. 1997), poor abalone growth (Haaker et al. 1998) and possibly decreased abalone egg production. Perhaps as a result of oceanographic conditions recruitment is highly variable in time and space (McShane & Smith 1991). If females have just a few years to spawn prior to growing into the fishery, some females may not spawn during this time if oceanographic conditions remain unfavorable. In fact, minimum size limits failed to prevent the collapse of abalone populations in

TABLE 3.

southern California (Tegner et al. 1989, Karpov et al. 2000) and elsewhere (Shepherd & Rodda 2001, Shepherd et al. 2001).

Evidence for Limited Reproductive Senescence

The largest individuals had the most (80% to 90%) necrotic eggs (Table 3, Fig. 4) suggesting the onset of reproductive senescence. On average, individuals in the largest size class had 40% necrotic eggs, the most of any of the size classes (see Table 3). Legal size abalone from this same date had less than 20% necrotic eggs. Histologic examination of female ovaries ($n = 34$) from VDSP indicated that in August 2001 only 12% of the eggs were necrotic, suggesting August is not a period of unusually high percentages of necrotic eggs. Few studies however, have examined reproductive senescence in mollusks, with freshwater mussels showing reproductive senescence (Downing et al. 1993), whereas marine quahog clams did not (Walker 1994).

Egg production capacity of very large female abalone (>215 mm) is still high, despite having high percentages of necrotic eggs. The size class with the greatest number of mature eggs per female abalone was the largest size class (220–260 mm) (see Table 3, Fig. 4), suggesting that even with reproductive senescence, the largest females are still capable of producing millions of eggs. It is unknown, however, if these females spawn successfully relative to smaller females or if the eggs produce viable, high quality larvae.

Egg Conservation and Reserves

One way to maintain egg production would be to exclude large females from the fishery using upper size limits or area closures. Legal size abalone (± 1 SD of the peak 215 mm) have the potential to generate 68% of the egg production (see Fig. 4). As in other recreational trophy fisheries however, where large animals are highly prized, the addition of an upper size limit may not have popular support. While reserves may benefit the fishery in the

north, these areas were largely absent in the south where stocks collapsed. The south also had additional abalone fishing pressures compared with the north because much of the coast is accessible, ocean conditions are frequently favorable and the use SCUBA was permitted for abalone fishing. The few reserves in the south such as the Anacapa Island Ecological Reserve (McArdle 1997) did function to protect large abalone and was shown to have the potential for increased egg production compared with neighboring fished areas (Rogers-Bennett et al. 2002).

The fishery in the north seems to be sustainable, perhaps in part due to protection of a portion of the stock in reserve areas and a large *de facto* reserve (both at deep depths [<8.5 m] and along inaccessible portions of the coast), which may be the key for sustainability as has been suggested in other fisheries (Walters & McGuire 1996). Inside established reserves in the north more juvenile abalone have been found compared with fished areas (Rogers-Bennett & Pearse 2001). If large abalone are to be protected and allowed to spawn, then maintaining reserves will need to remain a top priority for management, recreational divers and wildlife protection.

ACKNOWLEDGMENTS

Thank you to the recreational abalone divers along the north coast who participated in the study and allowed us to sample their abalone. Thanks to all the abalone creel samplers and the dive team of the California Department of Fish and Game. The authors thank Carolyn Friedman, Jim Moore, Thea Robbins, and Beverly Braid for their histologic assistance. Thanks to Patty Wolf and Eric Larson of the CDFG. This work was funded in part by the Recreational Abalone Advisory Committee and the recreational abalone stamp. The Bodega Marine Laboratory provided logistic support. Contribution number 2199, Bodega Marine Laboratory, University of California Davis.

ABSTRACT An innovative method was developed to quantitatively measure the attractiveness of cultured diatoms for early stages of abalone larvae settlement. Larvae of the abalone *Haliotis discus hannai* were offered, in a petri dish, a choice of several food patches, each made of a diatom monoculture layer. The distribution of the larval settlement on the patches of 17 diatom species was determined. *Nitzschia laevis* induced the most abalone larvae settlement, followed by *Navicula cf. lenzii* and *Amphora luciae*. The attractiveness of these diatoms for abalone larvae settlement was not directly related to algal biochemical composition or algal color. It is suggested that compounds excreted by algal cells determine their inductive properties for larval settlement. The larval chemosensory response depends on the concentration of these inductive substances. Sonicated diatom cell suspensions strongly induced larvae attachment, whereas dilute suspensions did not. Boiling settlement-inductive sonicated diatom cell suspensions did not affect their induction ability, implying that native proteins are not essential for the response. Aspartic acid was the only free amino acid excreted by two tested diatoms. It was also the only pure amino acid found inductive for larval settlement. It is therefore suggested that aspartic acid is a component of the settlement induction complex.

KEY WORDS: abalone, *Haliotis discus hannai*, larvae settlement, larval feeding, abalone, diatoms, mariculture

INTRODUCTION

The process of abalone larval settlement consists of several characteristic behaviors. Descent and exploration of the settlement substrata by the swimming larva is followed by attachment, which includes inspection and orientation at a favorable spot, and is concluded finally by metamorphosis (Seki & Taniguchi 1996, Seki 1997). The induction of larval settlement is a most critical stage in abalone recruitment in the wild and in seed production in culture. Abalone larvae require highly specific cues for attachment and metamorphosis stimulation (Morse & Morse 1984, Morse 1985, Roberts 2001). The absence of cues lead to low settlement rates and low survival in early post larval growth stages (Searcy-Bernal et al. 1992, Slattery 1992, Roberts et al. 1999, Daume et al. 1999, Takami et al. 2002). A better understanding of the settlement processes and the identification of a reliable approach for efficient recruitment and early growth in abalone larvae, are therefore of paramount importance for furthering both abalone recruitment research and abalone commercial reproduction.

Substances that have been reported to induce settlement in abalone larvae are crustose and coralline algae (Morse & Morse 1984, McShane 1992, Shepherd & Turner 1985), diatom layers (Slattery 1992, Takami et al. 1997, Daume et al. 1999), chemicals like GABA [gamma-amino butyric acid] (Morse 1985, Trapido-Rosenthal & Morse 1986, Morse & Morse 1984, Morse & Morse 1988), abalone mucus trails (Slattery 1992, Searcy Bernal et al. 1992, Seki & Taniguchi 1996, Seki 1997, Takami et al. 1997,

Bryan & Qian 1998), and bacterial films (Bryan & Qian 1998, Roberts 2001).

The induction of the settlement process in larval abalone *Haliotis rufescens* on crustose red macroalgae (such as *Lithothamnium californicum*) is based on chemosensory recognition of morphogenic and regulatory molecules (such as amino acids), occurring on the macroalgae outer surfaces and the surrounding water (Morse & Morse 1984, Trapido-Rosenthal & Morse 1986, Morse 1992).

Naturally recruited diatom films have long been used to induce larval settlement in abalone hatcheries around the world, but with a limited awareness or management of suitable settlement-inductive species and the properties that make them attractive to abalone larvae (Roberts 2001). Understanding the factors that regulate effective settlement, post larval growth, and the selection of cultivable diatoms that promote it, are therefore essential (Matthews & Cook 1995, Roberts 2001).

Diatoms release into their surrounding water substances that can induce settlement (Helebust 1974, Admiraal et al. 1986, Searcy-Bernal et al. 1992). It is hypothesized that the selective settlement of abalone larvae on a film of a certain species of algae is associated with larval-attracting chemicals, which "attractive" algae have on their cellular exterior or secrete into the water around them (Kuehn 1997). Such chemicals can create gradients detectable by small aquatic animals even in turbulent water (Finelli et al. 1999), and abalone larvae are known to have the physiologic ability to sense them (Morse & Morse 1984, Morse & Morse 1993, Morse 1992, Baxter & Morse 1992). This article describes a method developed to quantitatively measure the preference of swimming larvae for attachment onto a range of cultured diatoms (the term "settlement" is used henceforth, even though metamorphosis was not studied). "Attractive" and "not attractive" diatoms were selected by this method and then used to probe the chemical basis for the chemosensory settlement response of abalone larvae.

This work was supported by the Israeli Ministry for National Infrastructures (N.G., M.S. and A.N.), by grants from the European Commission (M.S. and A.N.) and NIH/NIGMS 08168-22 (J.J.L.).

MATERIALS AND METHODS

Larval Culture

Larvae of *Haliotis discus hannai* were obtained from an in-house abalone hatchery in Eilat, Gulf of Aqaba, Red Sea. Adults were induced to spawn using ultraviolet light (Kikuchi & Uki 1974). Fertilized eggs were collected and transferred into 20-L culture aquaria at a concentration of 12 eggs per mL. Rafamycin antibiotic was added at a concentration of 1.5 mg/L. Hatched larvae were kept at 22°C, with a 12 L: 12 D light cycle (60–70 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$), for 4–5 days, until they were competent for settlement. Larval competency was assessed based on swimming behavior, as described in Seki and Taniguchi 1996. The competent larvae were then used for the settlement preference experiments.

Diatom Cultures

Cultures of benthic diatoms were isolated from local waters and elsewhere (Table 1). Diatom cultures were made axenic by an antibiotic mixture of Penicillin G (800 $\mu\text{g/mL}$), Ampicillin and Streptomycin (400 $\mu\text{g/mL}$) and Chloramphenicol (160 $\mu\text{g/mL}$) for 24 hours (Ucko 1996). The cultures were then transferred into Gentamycin sulfate (200 $\mu\text{g/mL}$) for 24 hours. The axenity of the treated cultures was confirmed by plating them on a rich nutrient agar (DIFCO) petri dishes, which can clearly show any bacterial contamination. The axenic algal cultures were cultured at 22°C to 24°C in a slightly modified f/2 medium (Guillard & Ryther 1962). The cultures were maintained in test tubes under continuous light ($\sim 110 \mu\text{mol photons m}^{-2}\text{s}^{-1}$).

For the settlement preference experiments, algae were axenically grown on a Bacto-agar (DIFCO) solid medium, which was prepared with modified f/2 medium as mentioned earlier, or with artificial sea water (ASW) (Jones et al. 1963) enriched with silica. Petri agar dishes were inoculated by spreading the diatoms uniformly on the agar surface and left to grow for about 2 weeks, when a uniform diatom layer was formed.

The Experimental System, Developed to Quantify Larval Settlement Preference

Preparation of the Experimental Petri Dishes

The larval settlement preference experimental system was a modification of the "cafeteria" method used by Lee et al. (1977). The top of an alcohol-sterilized 16 mm test tube was used to remove diatom-covered agar plugs from the diatom culture dishes and to insert them into the same size holes in Agarose agar (Sigma) layers in the experiment dishes. These were prepared by pouring 25 mL of 1% Agarose agar into 90 mm petri dishes, in thin layers. Preliminary experiments showed that other types of agar negatively affected the settlement and growth of the larvae. After cooling and hardening of the agar, four plugs were cut out and removed from the Agarose agar layer in each dish with an alcohol-sterilized 16 mm test tube. Three of the round empty spaces that remained were filled, as described earlier, with diatom covered Bacto-agar plugs of the same size, whereas the fourth empty space was filled with a control Bacto agar plug, without any algal layer (Fig. 1). Usually 10 replicates were prepared of each experimental dish, with the same three diatom species and a control plug. Special care was taken to reduce microbial contamination during the experiments once the axenity was compromised with the addition of the larvae. The experiments took place in a clean culture room and manipulations took place in a sterile laminar-flow hood.

Assessment of the Settlement Preference of Larval Japanese Abalone onto Layers of Different Diatoms

Forty mL of 32 ppt filtered sea water was carefully pipetted onto the surface of the Agarose agar layer in the experimental dishes, to make aqueous layers (0.6 cm in depth) for the swimming larvae. Competent larvae (200–250) were gently introduced to the center of each dish. The larval density was selected after a set of preliminary tests that suggested this density as optimal for counting and statistics, with no harm to the settlement process. The dishes were left covered, at 22 °C and under continuous light ($\sim 60 \mu\text{mol photons m}^{-2}\text{s}^{-1}$). These conditions involved minimal technical difficulties in the laboratory, and fell within the range of

Figure 1. A photograph describing an experiment with 10 replicate petri dishes, used for the measurement of settlement preference by abalone larvae. Each dish contains 3 patches of the same 3 diatoms and a no-diatom control patch (see Materials and Methods for details).

conditions reported in the literature. No preliminary tests were made to optimize temperature and light conditions.

Counts of settled larvae on top of the algal patches were carried out using a dissecting microscope several times during 24 hours. Attractiveness of a certain algal species to the larvae was determined by the number of larvae that settled (even if metamorphosis was not completed) on its patch relative to the number of larvae settled on the other diatom patches and on the control patch up to a certain time (usually 10 h) after initiation of the experiment. Seventeen species of algae were tested for larval settlement preference in 50 experiments, each consisting of 10 replicate petri dishes, each with the same group of three diatoms.

Elucidation of Possible Factors Influencing Settlement Preference by the Larvae of the Japanese Abalone

Settlement Preference of the Larvae onto Sonicated and Boiled Diatom Cells

This experiment used the settlement preference measurement system described above to evaluate a possible linkage between algal internal biochemical composition and larval preference to settle on it. Concentrated algal cells were broken with an ultrasonic cell disruptor (Microson) for 5 minutes (microscopy check assured cell disruption) and then mixed with cooled (40–45 °C), still liquefied Bacto agar. Larval settlement preference was tested towards *Nitzschia laevis* (2.05×10^6 cells/plug), which in its native state had been found very attractive to the larvae, and *Amphora cf. tenerrima* (2) (3.9×10^5 cells/plug), which in its native state had been found to be unattractive or even repulsive to the larvae.

A second experiment was conducted as earlier stated, but the sonicated cells were boiled for 15 minutes before mixing with agar, to denature the proteins. The aim of this experiment was to determine the role of native proteins in attractiveness to the larvae.

Settlement Preference of the Larvae onto Agar Plugs Soaked with Algal Growing Medium and Amino Acids

Settlement preference of abalone larvae was tested towards liquid culture media in which algae had been axenically grown. Algal cultures were centrifuged (3000 rpm for 5 min in a clinical centrifuge) and the clear media were then filtered through a Nucleopore filter (0.2 μ) to remove any cell debris, and used with 1% agar to prepare an agar layer from which plugs could be cut for the assays.

Settlement preference of the larvae was also tested towards agar plugs soaked with solutions (final concentration in agar 10 mM) of the following L-amino acids: methionine, threonine, serine, phenylalanine, tryptophan, glycine, DL-alanine, proline, betaine, leucine, taurine, valine, cysteine, histidine, ornithine, arginine, lysine and aspartic acid (All Sigma reagent grade).

Statistical Analyses

The data were compared by ANOVA (one way) with Duncan's multiple range test. Results in percentages were arcsine square root-transformed prior to ANOVA to homogenise variances (Sokal & Rohlf 1969).

The Effect of Light on the Settlement of Abalone Larvae

Settlement preference of abalone larvae was tested towards agar plugs with three different sonicated algal species (made as

earlier stated). Two series of 10 replicate algal dishes were made. One set was put in the dark, and the other in light.

RESULTS

Assessment of the Settlement Preference of Larval Japanese Abalone (*Haliotis discus hannai*) onto Layers of Different Diatoms

In most cases larvae settled during 10 hours from the experiment initiation (Fig. 2). Strong settlement stimulants, like sonicated cell suspensions, speeded up the settlement to 1.5 hours to 5 hours.

The larval abalone preferred, by a large margin, to settle on patches of *Nitzschia laevis* in each of the experiments in which this diatom was offered (Table 2). On average, almost half the larvae settled on *N. laevis* in each relevant individual experiment, in comparison to much smaller fractions on the other diatoms offered and on the control (Table 3). Significant (1-w ANOVA, $P < 0.05$) preference of the abalone larvae for the diatoms *Navicula cf. lenzii* and *Amphora luciae* was obtained in 82% and 75% of relevant experiments, respectively (see Table 2). On the average, about a quarter to a third of the larvae preferred these two diatoms in each relevant individual experiment (Table 3).

Nitzschia laevis (the symbiont clone) and *Amphora coffeiformis* were also found attractive to the larvae in individual experiments (see Table 3). However, over half of the diatoms tested were not found to be attractive to larval settlement in most of the experiments (Tables 2 and 3).

Settlement of Japanese Abalone Larvae on Sonicated Diatom Cell Suspensions

The larvae preferred by a large margin ($P < 0.001$) to settle onto *Nitzschia laevis* layers rather than onto *Amphora cf. tenerrima* (2) layers or the control (no algae) (Fig. 3). Whole cells of *A. cf. tenerrima* (2) were found unattractive to larvae in this experiment and others (see Table 2). On the contrary, the abalone larvae showed a strong preference (70% of the settled larvae; $P < 0.001$) for settlement onto sonicated cells of the same *A. cf. tenerrima* (2).

Figure 2. Number of Japanese abalone larvae settled onto patches of 3 diatoms (*Nitzschia laevis*, *Navicula cf. vimnoides* and *Amphora tenerrima*) and a control (no algae) in the course of 16 h. Means (\pm S.E.), $n = 8$.

TABLE 2.

The attraction rank (column A) of each of the examined diatoms (column B). The diatoms were ranked according to their attractiveness to larvae, based on the number of experiments each diatom was offered to abalone larvae (column C), and the number of experiments (with % of experiments from column C in parenthesis) in which larvae significantly (1-w ANOVA, $P < 0.05$) preferred to attach onto that diatom species (column D).

A Attraction Ranking	B Diatom Species	C Number of Experiments	D No. of Experiments with Significant Attraction
1	<i>Nitzschia laevis</i>	31	31 (100%)
2	<i>Navicula cf lenzii</i>	28	23 (82%)
3	<i>Amphora luciae</i>	12	9 (75%)
4	<i>Nitzschia laevis</i> (symbiont clone)	11	7 (64%)
5	<i>Amphora coffeiformis</i>	6	4 (66%)
6	<i>Amphora</i> sp. (1)	6	4 (67%)
7	<i>Navicula cf viminoides</i>	8	4 (50%)
8	<i>Navicula</i> sp. (1)	4	2 (50%)
9	<i>Navicula</i> sp. (2)	2	1 (50%)
10	<i>Navicula salinicula</i>	9	3 (33%)
11	<i>Amphora</i> sp. (2)	7	2 (28%)
12	<i>Amphora</i> sp. (3)	7	2 (28%)
13	<i>Amphora cf tenerrima</i> (1)	9	1 (11%)
14	<i>Amphora</i> sp. (4)	5	1 (20%)
15	<i>Navicula</i> sp. (3)	11	1 (9%)
16	<i>Amphora cf tenerrima</i> (2)	5	0
17	<i>Amphora</i> sp. (6)	5	0

Surprisingly, the settlement on sonicated *N. laevis* was much lower than that on *A. cf tenerrima* (2) and in one experiment it did not differ from the control (no algae) (see Fig. 3).

The temporal dynamics of the settlement process were also different with the sonicated diatoms. When comparing larval settlement onto whole cells and onto sonicated cells in the same petri dish, larvae explored and attached first (after 1.3 h) onto the sonicated cells, and gradually over time moved to settle onto the whole cells (Fig. 4). After 22 hours, larval settlement onto patches of intact cell layers was significantly (1-w ANOVA, $P < 0.001$) higher than onto patches of the sonicated cell suspensions or the control (no algae).

Settlement of Abalone Larvae on Boiled Sonicated Diatom Cells

Larval preference for settlement onto sonicated cells of three of the four diatom species tested was not significantly affected (1-w ANOVA, $P > 0.05$) by boiling them (Fig. 5). Only with sonicated *Amphora luciae* cells, did the larval preference significantly drop (1-w ANOVA, $P < 0.001$) after boiling, even though it still remained significantly above the preference (1-w ANOVA, $P = 0.001$) for the control (no algae) (Fig. 5).

Settlement of Japanese Abalone Larvae on Agar Plugs Soaked with Algal Growing Medium and Amino Acid Solutions

The abalone larvae settlement on agar plugs soaked with algal growing medium, in which attractive diatoms had been grown, did

not produce significant results (1-w ANOVA, $P > 0.05$) (Table 4). Settlement on agar plugs soaked with 10 mM of aspartic acid was consistently much (13 times) higher than on the control (no algae) plug ($P < 0.001$ Table 5). However, settlement on 16 other amino acids tested, singly and in mixtures, could not be distinguished (1-w ANOVA, $P > 0.05$) from the control (see Table 5).

The Effect of Light on the Settlement of Abalone Larvae

There was no significant effect of light (1-w ANOVA, $P > 0.05$) on the settlement of larvae (Fig. 6).

DISCUSSION

Post larvae of abalone are able to distinguish between diatom species, feeding on some and avoiding others (Norman-Boudreau et al. 1986, Matthews & Cook 1995, Siqueiros-Beltrones & Voltolina 2000). This behavior is similar to that which has been observed in many meiofauna that were attracted to and retained by patches of micro-algae that they selected (Lee et al. 1977). In this context it was not surprising that the larvae of *Haliotis discus hamai* in our experiment preferred to selectively attach and settle on some of the diatom patches offered to them but not on others. The chemosensory nature of the process, by which swimming abalone larvae select where to attach and where to settle, has been confirmed by the success of our novel "cafeteria" method by which "good" diatoms were selected. This method was based on the ability of abalone to sense and select the site of settlement and source of food according to several proposed environmental cues (Morse 1985, Morse 1992, Baxter & Morse 1992, Searcy-Bernal et al. 1992, Fleming 1995, Bryan & Qian 1998, Roberts 2001).

Not many diatoms are known to be consistently suitable for abalone larval recruitment (Roberts 2001). Most of the diatoms we tested were indeed unsuitable (as has also been reported in Daume et al. 1999), even though they formed flat colonies, which had been reported as suitable for abalone larval settlement (Kawamura 1996). Nevertheless we have found three highly attractive diatoms: *Nitzschia laevis*, which was by far the best, followed by *Navicula lenzii* and *Amphora luciae*.

In accordance with the results of the study by Morse and Morse (1984) on *Haliotis rufescens* larvae, the cue that allows the Japanese abalone larvae to select one diatom over another for settlement was not visual or physical, but probably chemical. Apparently, the larvae swim towards settlement-inducing substances that are released by the diatoms and descend around them (Searcy-Bernal et al. 1992). If the diatoms are nutritious, the larvae attach and metamorphose; otherwise they ascend and swim on.

Sonication that causes release of cellular material into the surrounding water enhanced *Amphora cf tenerrima* (2) attractiveness for larval settlement, whereas intact cells were not found attractive. Morse and Morse (1984) obtained similar results in their study with *Haliotis rufescens* by surface abrasion of the seaweed *Porphyra* sp. Evidently, sonication or abrasion of "non-attractive" algae releases or speeds up the release of attractive substances that are tightly contained naturally in their intact cells.

The high preference of the abalone larvae to descend onto broken (sonicated) cells, in contrast to the lack of descent onto plugs soaked with algal growth medium, implies that attachment and settlement are concentration dependent and may explain the

TABLE 3.

The settlement preference of Japanese abalone larvae for different diatoms in 8 typical positive comparisons, calculated for species that had been found significantly (1-w ANOVA, $P < 0.05$) attractive in 50% or more of the experiments in which they had been offered. Means include all experiments with the specific combination. Each combination tested attraction toward a control of Bacto-agar plus without algae, and a reference plug with a highly attractive alga (*Nitzschia laevis* or *Navicula lenzii*).

link between density and age of an algal layer and its suitability for settlement, as reported in previous studies (Kawamura & Kikuchi 1992, Daume et al. 1999).

The process of larval swimming, descent on several sites and attachment to a certain diatom patch as seen in our work and noted earlier by others (Seki 1997, Bryan & Qian 1998) is a serial cue process. Our data and observations confirm that in the process of substratum exploration, the descent of larvae to a certain spot usually depends on a cue, different in kind or in quantity from the cue for attachment and metamorphosis. The attachment is most probably induced by the mutual and perhaps synergistic action of several cues (Trapido-Rosental & Morse 1986). If larvae are given a choice, attachment and metamorphosis will most probably depend on specific attractive and repellent compounds (see below), in addition to the obvious cue of the nutritive value of the patch. Repellent or harmful substances can reduce descent or elicit ascent of the larvae (Seki 1997, Bryan & Qian 1998, Roberts 2001). This can explain why larvae that quickly descended in large numbers on a sonicated diatom suspension patch, eventually moved on and settled on patches of intact algae, apparently nutritive even though comparatively less attractive for settlement. Seki and Taniguchi

(1996) and Takami et al. (1997) found similar results with mucus induction: abalone larvae settled preferentially on trails of apparently more nutritive mucus, secreted by juvenile or adult abalone during grazing of diatoms, than on mucus secreted by adults during crawling without feeding. Aspartic acid strongly induced descent and attachment of swimming larval abalone. It was also the only free amino acid traced in the growth media of two diatoms, the attractive *Nitzschia laevis* and the unattractive *Amphora cf tenerrima*.

TABLE 4.
Larval settlement, tested toward agar layers made with liquid media in which diatoms had been grown, in comparison to whole cell diatom layers on agar. Mean number of settled larvae \pm SE; $n = 10$; data with the same letter indicate treatments that are not significantly different (ANOVA, Duncan's multiple range test, $P > 0.05$).

<i>Amphora cf tenerrima</i> (2)	28 \pm 3.2 b	29 \pm 3.4 a
Control	28 \pm 3 b	33 \pm 2.8 a

Figure 3. Settlement of Japanese abalone larvae on agar plugs covered by whole diatom cells in comparison with agar plugs covered by sonicated cells (mixed in agar plugs) of the same diatoms in different dishes. Means (\pm S.E.), $n = 10$; data with the same letter indicate treatments that are not significantly different (ANOVA, Duncan's multiple range test, $P > 0.05$).

Figure 4. Settlement of Japanese abalone larvae on layers of whole diatom cells in comparison with sonicated diatom cells (mixed in agar plugs) in the same dish. Means (\pm S.E.), $n = 10$; data with the same letter indicate treatments that are not significantly different (ANOVA, Duncan's multiple range test, $P > 0.05$).

errima (2). However, the concentrations of aspartic acid in these media were two orders of magnitude lower than inside algal cells, and three orders of magnitude lower than the level needed to induce larval attachment in our experiments. Aspartic acid might therefore be only one of several factors concurrently involved in larval settlement induction. The rate of the chemical release to the water by the intact cells and the sharpness of the resulting chemical concentration gradients around them might also be important aspects, as suggested by the inability of the other diatom (*A. cf*

Figure 6. Settlement of Japanese abalone larvae on sonicated cells (mixed in agar plugs) of different diatom species, in dark and light experiments. Means (\pm S.E.), $n = 10$; **N. laevis* = *Nitzschia laevis*; *N. lenzii* = *Navicula cf lenzii*; *A. luciae* = *Amphora luciae*.

Figure 5. Settlement of Japanese abalone larvae on boiled sonicated cells (mixed in agar plugs) in comparison with the same sonicated cells, un-boiled (mixed in agar plugs), in the same dish. Means (\pm S.E.), $n = 10$; data with the same letter indicate treatments that are not significantly different (ANOVA, Duncan's multiple range test, $P > 0.05$); **N. laevis* = *Nitzschia laevis*; *A. tenerrima* (2) = *Amphora cf tenerrima* (2); *N. lenzii* = *Navicula cf lenzii*; *A. luciae* = *Amphora luciae*.

tenerrima (2)) to attract larval descent with this amino acid in its surroundings. Chemical gradients that are sufficient for chemosensory attraction of larvae can be maintained even in turbulent water, let alone still water as in these experiments (Turner et al. 1994).

Complex native proteins are unlikely to be responsible for the attractiveness of a diatom to larval settlement, because heat denaturation of proteins in sonicated diatom suspensions hardly affected the results of the settlement experiments. Still, small peptides or free amino acids, not affected by heat-denaturation and therefore not excluded by the boiling procedure, have been proposed as possible as chemical cues for abalone larval settlement (Morse & Morse 1984, Morse & Morse 1988, Morse 1985).

Layers made of certain diatoms, such as the three species selected in the research reported here, but not many others, apparently provide the swimming larvae with the whole battery of cues they

TABLE 5.

Larval settlement tested towards solutions (10 mM final concentration) of four amino acids soaked into agar plugs.

Amino Acid	Attracted Larvae (%)
Alanine	4 \pm 1

need for descent, attachment, metamorphosis, and nutritious feeding. Layers of diatoms such as those selected here improve attachment and settlement and supply proper nutrition for early post larval stages. These qualities greatly improve survival and growth of the abalone early post larvae (Slattery 1992, Searcy-Bernal et al. 1992, Matthews & Cook 1995, Daume et al. 1999, Roberts 2001). This understanding helps explain the interrelationship between

diatom biodiversity and the recruitment of animals, such as abalone, both in natural settings and in aquaculture.

TAXONOMIC APPENDIX

The isolates used in this study have been identified to the closest described taxa. We recognize that species concept in dia-

toms has been interpreted in many ways. Some have very rigid "morpho-species" concepts that allow very little deviation from the type specimen (e.g., Clavero et al. 2000) whereas others (e.g., Lee et al. 2000) have looked at a wide variance in overlapping populations obtained from different field collections. We acknowledge the problem, as it relates to our isolates, but do not wish to resolve this conundrum here.

Some of the diatoms were easier to identify than were others. Four species were problematic. We chose to identify the organism #3 in Table 1 as *Navicula* cf *vinuoides* Giffen. The clone culture we used fit the original description and illustrations of the species.

Navicula cf *lenzii* Hustedt 1945 was described as a freshwater species. In his 1961 monograph (see Literature Cited), Hustedt illustrated and described the variations he considered as belonging to this taxon. Although we would be skeptical to find a freshwater species in a eutrophic marine environment, the species with which we worked is more closely related to this taxon than to any other.

Organisms numbered 5 and 6 in Table 1 were referred to *Amphora* cf *tenerrima* Aleem and Hustedt. They were morphologically distinct from each other in SEM micrographs, but resembled the original light microscopic description of the species by Aleem and Hustedt.

LETHAL LEVELS OF DISSOLVED OXYGEN FOR *HALIOTIS DIVERSICOLOR SUPERTEXTA* AT DIFFERENT SALINITY LEVELS

SHA-YEN CHENG,¹ YIN-HUNG CHANG² AND JIANN-CHU CHEN^{2,*}

¹Department of Environmental Biology and Fisheries Science and ²Department of Aquaculture, College of Life and Resource Sciences, National Taiwan Ocean University, Keelung 202, Taiwan, Republic of China

ABSTRACT The abalone *Haliotis diversicolor supertexta* juveniles (shell length 3.51 ± 1.10 cm) were exposed to different concentrations of dissolved oxygen (DO) using the static renewal method at different salinity levels of 25‰ (g kg⁻¹) and 35‰ at pH 8.04 and 22°C. The 72-, 84-, and 96-h LC₅₀ values of DO on *H. diversicolor supertexta* juveniles were 1.56, 1.76, 2.02 mg L⁻¹ at 25‰ and 1.43, 1.65, 1.83 mg L⁻¹ at 35‰, respectively. As the salinity decreased from 35‰ to 25‰, susceptibility to DO increased by 107%, 107%, and 110% after 72-, 84-, and 96-h exposure, respectively. The relationship between LC₅₀ of DO (mg L⁻¹), salinity (S) and exposure time (T) in the range 72–96 h is as follows:

$$LC_{50} = 0.541 - 0.012S + 0.018T \quad (R^2 = 0.637)$$

KEY WORDS: dissolved oxygen, *Haliotis diversicolor supertexta*, salinity, tolerance

INTRODUCTION

Taiwan abalone (also known as small abalone) *Haliotis diversicolor supertexta* is commercially important in Taiwan as well as in the southeast coast of mainland China as a primary cultured species. For growth, Chen (1984) has observed that salinity in the range 30–35‰ and temperature in the range 24–30°C are the optimal levels. Culture of *H. diversicolor supertexta* has expanded greatly since 1986 due to successful artificial propagation and development of multiple-tier basket systems in grow-out farms (Yang and Ting 1986, Chen and Lee 1999).

Since late 2000, farmers have experienced mass mortality of abalone reared in the multiple-tier basket systems in the grow-out ponds and settlement failure of spat larvae in the nursery ponds. The bacteria *Vibrio alginolyticus* and *V. parahaemolyticus* isolated from the hemolymph of moribund abalone have been documented to cause vibriosis leading to death of abalone in warmer water temperatures (Liu et al. 2000, Lee et al. 2001). As a result, the farmed production of abalone in Taiwan declined from 2497 tons in 2001 to 1089 tons in 2003.

Yang and Ting (1989) reported that dissolved oxygen (DO) should be maintained higher than 5 mg L⁻¹ for the optimal growth of *H. diversicolor supertexta*. They also reported that the oxygen consumption of this species maintained at 32‰ and 30°C was 1.3 times that maintained at 32‰ and 25°C. Fallu (1991) reported that abalones require DO greater than about 3–4 mg L⁻¹. It is very common that the pond water in multiple-tier basket systems may become hypoxic or even anoxic due to respiration of animals and decomposition of accumulated organic matter such as unconsumed food and feces. Therefore, concentrations of DO in pond water and its lethal levels on abalone are of primary concern.

Lethal levels of DO have been reported for a number species of penaeid shrimps including kuruma shrimp *Marsupenaeus japonicus* (Egusa 1961, Tournier 1972), caramote prawn *Melicerus kerathurus* (Tournier 1972), tiger shrimp *Penaeus monodon* (Liao & Huang 1975, Allan & Maguire 1991), southern white shrimp *Litopenaeus setiferus* (MacKay 1974), and northern brown shrimp

Farfantepenaeus aztecus (Martínez et al. 1998). Concerning the mollusks, Miller et al. (2002) reported that the 96-h LC₉₀ (90% of animal killed after 96 h) of DO on the Atlantic surf-clam *Spisula solidissima* was 0.3 mg L⁻¹. Tamai (1993) reported that the semelid small bivalve *Theora fragilis* survived DO as low as 1.3–1.4 mg L⁻¹ at least for four days. Temperature has been reported to affect the tolerance of low DO on zebra mussel *Dreissena polymorpha* and Asian clam *Corbicula fluminea* (Johnson & McMahon 1998). However, with a few minutes of literature searching, we found no information available on the lethal level of DO on marine invertebrates at different salinity levels. The purpose of the current study is to estimate the lethal level of DO on *H. diversicolor supertexta* at 25‰ and 35‰.

MATERIALS AND METHODS

Seawater and Test Solution

Seawater pumped from the Keelung coast adjacent to the National Taiwan Ocean University was adjusted to 35‰ (g kg⁻¹) and 25‰, with municipal water dechlorinated with sodium thiosulfate, and then filtered through a gravel and sand bed by air-lifting and aerating for three days before use. The concentration of DO in water was regulated with nitrogen gas that was bubbled into the water to produce a series of DO that ranged from 6.87 to 7.46, 5.12 to 5.88, 3.19 to 3.80, 2.19 to 2.77, and 1.24 to 1.62 mg L⁻¹ with an average of 7.11, 5.53, 3.45, 2.47, and 1.44 mg L⁻¹, respectively. These served as test solutions.

Animals

H. diversicolor supertexta were obtained from a commercial abalone farm in Ilan, Taiwan, and acclimated in the laboratory with salinity of 35‰ for two weeks prior to experimentation. The abalones were divided randomly into two groups in the same salinity and then adjusted 2‰ each day to reach two different salinity levels of 25‰ and 35‰. After the abalones reached the expected salinity levels, they were reared for one more week. The mean (±SD) wet body weight and shell length was 4.12 ± 0.9 g and 3.51 ± 1.10 cm, respectively, with no significant difference among treatments.

Lethal Effect of Dissolved Oxygen

Short-term LC_{50} (median lethal concentration) toxicity tests were carried out according to the methods described by the American Public Health Association et al. (1985). Abalones were sampled randomly from the holding tanks and transferred to test solutions. Bioassay experiments to establish tolerance limits were conducted in 20-L glass flasks containing 10-L test solutions. Each tank contained 10 test abalones. Each test solution was renewed daily, in accordance with the static renewal method for toxicity tests (Buikema et al. 1982). There were three replicates for each test solution with a total number of 30 abalones (10 per replicate for each test solution). During the experiment, abalones were fed *Gracilaria tenuistipitata* daily. Water temperature was maintained at $22 \pm 1^\circ\text{C}$ and pH ranged from 7.87 to 8.12 with an average of 8.04.

Observations were usually made at 6-h intervals up to 168 h. Abalone that failed to respond to tactile stimulation when touched with a glass rod were defined as dead. The LT_{50} (median lethal time, hours required to kill half the population) was determined. Dead abalones were removed daily. The concentration response of test organisms was determined for LC_{50} (median lethal concentration) value of dissolved oxygen and their 95% confidence limits with a computer program (Trevors and Lusty 1985) based on a method described by Hubert (1980). The estimated probit line and the results of a chi-square (χ^2) test for goodness of fit were computed.

Statistical Analysis

The LC_{50} s of dissolved oxygen (DO) were subjected to one-way analysis of variance (ANOVA) followed by Duncan multiple range test (Duncan 1955). Relationship between survival, salinity, DO concentration, and exposure time (hours) and the relationship between LC_{50} of DO, salinity, and exposure time were tested using the General Linear Model procedure and Regression Procedure, version 6.03, Statistical Analysis System (SAS) computer software (SAS 1998). All statistical significance tests were at the $P < 0.05$ level.

RESULTS

All abalones survived in the test solutions at 5.53 and 7.11 mg L^{-1} DO at all salinity levels after 168 h exposure. No abalone died in 1.44 and 2.47 mg L^{-1} DO after 36 h at 25‰. However, all abalones exposed to 1.44 mg L^{-1} DO at 25‰ died after 108 h. No abalone died in 1.44 and 2.47 mg L^{-1} after 24 h and 48 h, respectively, at 35‰. However, all abalones exposed to 1.44 mg L^{-1} DO at 35‰ died after 108 h (Fig. 1). There was a significant effect of DO, salinity, and exposure time on survival. There was also a significant interaction between the effects of salinity and DO and a significant interaction between the effects of DO concentration and exposure time on survival. There was no significant interaction between the effects of salinity and exposure time on survival. In salinity levels of 25–35‰, the relationship between survival (%), DO concentration (C), salinity (S), exposure time (T), and the interactions between salinity and DO concentration (SC), DO concentration and exposure time (CT) is as follows:

$$\text{Survival (\%)} = 123.125 + 0.340S - 1.439T - 7.340C - 0.054SC + 0.418CT \quad (R^2 = 0.858)$$

For the abalones exposed to 1.44 mg L^{-1} DO at 25‰ and 35‰, there was a significant effect of salinity and exposure time on

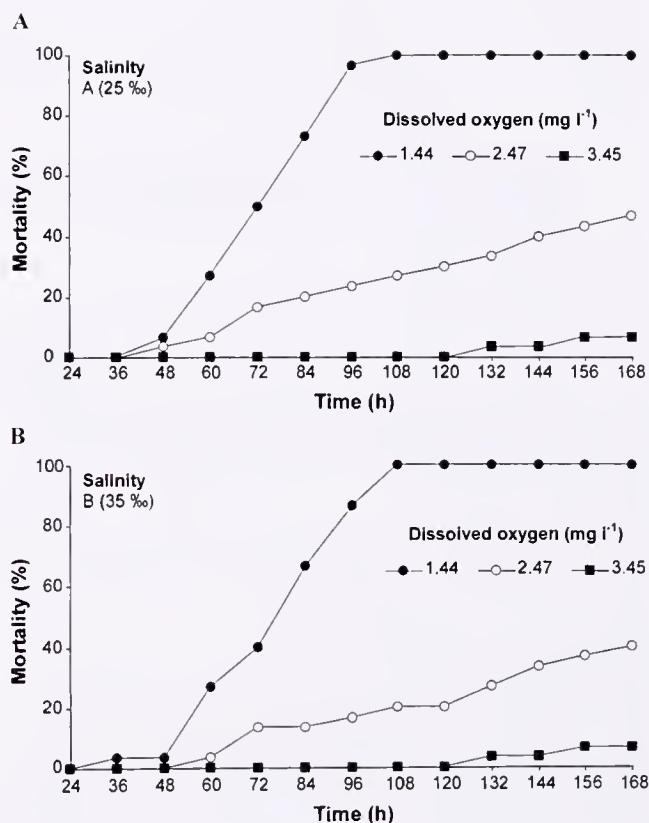

Figure 1. The percentage mortality of *Haliotis diversicolor supertexta* juveniles exposed to different dissolved oxygen consumption at (A) 25‰ (A) and (B) 35‰.

survival. However, there was no significant interaction between the effects of salinity and exposure time on survival. In 1.44 mg L^{-1} DO, the relationship between survival, S, and T is as follows:

$$\text{Survival (\%)} = 116.210 + 0.138S - 0.879T \quad (R^2 = 0.858).$$

For the abalones exposed to 2.47 mg L^{-1} DO at 25‰ and 35‰, there was a significant effect of salinity and exposure time on survival. However, there was no significant interaction between the effects of salinity and exposure time on survival. In 2.47 mg L^{-1} DO, the relationship between survival, S, and T is as follows:

$$\text{Survival (\%)} = 97.501 + 0.460S - 0.319T \quad (R^2 = 0.847).$$

In 25‰, the LT_{50} (median lethal time, hours) values of *H. diversicolor supertexta* juveniles exposed to 2.47 and 1.44 mg L^{-1} DO was 179 and 72 h, respectively, whereas in 35‰, the LT_{50} of abalone exposed to 2.47 and 1.44 mg L^{-1} DO was 204 and 75 h, respectively. The probit of mortality for *H. diversicolor supertexta* juveniles exposed to DO was linearly related to log DO at various exposure times (Table 1). A χ^2 test indicated that values of chi were less than the values in those tables, suggesting that the assumed lines were satisfactory (Trevors & Lusty, 1985).

The LC_{50} of DO values (and their 95% confidence limits) at different exposure periods for *H. diversicolor supertexta* juveniles are shown in Figure 2. At 72, 84, and 96 h, the LC_{50} values of DO were 1.56, 1.76, and 2.02 mg L^{-1} at 25‰ and 1.43, 1.65, and 1.83 mg L^{-1} at 35‰. Resistance of *H. diversicolor supertexta* juveniles to DO was 9.0%, 6.7%, and 10.3% less at 25‰ than that at 35‰ after 72, 84, and 96 h exposure. The LC_{50} of DO was inversely

* Number of concentration for calculation.

† Coefficient of determination.

related with salinity level on *H. diversicolor supertexta* juveniles. The LC₅₀ values of DO at 35‰ were significantly lower than those at 25‰ on *H. diversicolor supertexta* juveniles.

Statistical analysis indicated that there was a significant effect of salinity on LC₅₀ and exposure time on LC₅₀. However, there was no significant interaction between the effects of salinity and exposure time on LC₅₀. The relationship between LC₅₀ of DO (mg L⁻¹), S, and T is as follows:

$$LC_{50} = 0.541 - 0.012S + 0.018T \quad (R^2 = 0.637).$$

DISCUSSION

The sublethal concentrations of DO for selected marine and estuarine teleosts and invertebrates have been studied (Table 2).

Figure 2. LC₅₀ (median lethal concentration) of dissolved oxygen and its 95% confidence limits to *Haliotis diversicolor supertexta* juveniles exposed to different concentrations of dissolved oxygen at 25‰ and 35‰.

Reported 96-h LC₅₀ of DO on juvenile teleost ranged from 0.6 mg L⁻¹ for northern sea robin *Prionotus carolinus* to 1.6 mg L⁻¹ for summer flounder *Paralichthys dentatus* and striped bass *Morone saxatilis* (Miller et al. 2002). Reported 96-h LC₅₀ of DO on juvenile decapod crustaceans ranged from 0.7 mg L⁻¹ for daggerblade grass shrimp *Palaemonetes pugio* to 2.9–4.4 mg L⁻¹ for northern brown shrimp *F. aztecus* (Stickle et al. 1989, Allan and Maguire 1991, Miller et al. 2002). The 96-h and 168-h LC₅₀ of DO on blue crab *Callinectes sapidus* was 2.5–4.1 mg L⁻¹ and 2.3 mg L⁻¹, respectively (Stickle et al. 1989, Das and Stickle 1993). Reported 96-h LC₅₀ of DO on juvenile mollusc was 0.5 mg L⁻¹ for Atlantic surfclam *Spisula solidissima* at 28–32‰ (Miller et al. 2002) and 2.02 mg L⁻¹ and 1.83 mg L⁻¹ for *H. diversicolor supertexta* at 25‰ and 35‰, respectively, in the current study. These facts indicated that the abalone *H. diversicolor supertexta* was less tolerant to low DO than *P. monodon* and *S. solidissima* but was more tolerant to low DO than *F. aztecus* and *C. sapidus*. Liao and Huang

<i>Haliotis diversicolor supertexta</i>	35	96-h 1.83	Current study

(1975) reported that the lethal level of DO was 0.2–0.3 mg L⁻¹ for *P. monodon*. Allan and Maguire (1991) reported that all *P. monodon* juveniles exposed to 0.3 mg L⁻¹ were killed within 12 h. The current study indicated that *H. diversicolor supertexta* exposed to 1.44 mg L⁻¹ DO were killed within 108 h.

In addition to lethality, growth of *H. diversicolor supertexta* may be affected by low DO. Sediman and Lawrence (1985) reported that the level of DO at 1.2 mg L⁻¹ reduces significantly the growth, and the levels of DO higher than 2 mg L⁻¹ do not affect the growth of *P. monodon* and whiteleg shrimp *Litopenaeus vannamei*. Yang and Ting (1989) reported that DO should be maintained higher than 5 mg L⁻¹ for the optimal growth of *H. diversicolor supertexta*. However, we do not know the level of DO that affects the growth of abalone.

Most of the previous papers documented LC₅₀ values of DO for teleosts and invertebrates at one salinity level only. Abalones are generally cultured intensively in outdoor semi-static pond water or an indoor multiple-tier basket system with salinity varying from 25‰ to 35‰ (Chen and Lee 1999). Lin and Chen (2001) reported that the toxicity of ammonia to *L. vannamei* increased by 104% to 112% as salinity decreased from 35‰ to 25‰. Lin and Chen (2003) reported that the toxicity of nitrite to *L. vannamei* juveniles increased by 161% to 197% as salinity decreased from 35‰ to 25‰. Tsai and Chen (2002) reported that the toxicity of nitrate to *P. monodon* increased by 128% to 147% as salinity decreased from 35‰ to 25‰. Martínez et al. (1998) reported that the lethality of low DO to *L. setiferus* increased by 160% as salinity decreased from 38‰ to 15‰. The current study indicated that the lethality of low DO on *H. diversicolor supertexta* increased by 105% to 111% as salinity decreased from 35‰ to 25‰. Therefore, abalone and shrimp farmers should note the toxicity differences of ammonia, nitrite, nitrate, and low DO at different salinity levels when marking pond management.

In ponds, DO increases during the daytime due to the photosynthesis of phytoplankton and macrophytes and decreases during the nighttime due to the respiration of both plants and animals. It is not surprising that DO depletion may occur in abalone farms, especially in multiple-tier basket systems, due to poor water cir-

ulation. Species of the bacterial *Vibrio* genus are ubiquitous in the marine and estuarine environments. Disease outbreaks have been reported to be associated with increases in the *Vibrio* population of the cultured water (Sung et al. 1999). Challenging *H. diversicolor supertexta* with *V. parahaemolyticus* at 2×10^4 cfu abalone⁻¹ and placed in 35‰ water with different concentrations of DO, Cheng et al. (2004) observed that 72-h and 96-h LC₅₀ of DO was 4.71 and 5.17 mg L⁻¹, respectively. They also reported that the abalone exposed to DO at 3.57 mg L⁻¹ or lower showed decreases in hemocyte count, release of superoxide anion, and phagocytic activity and clearance efficiency to *V. parahaemolyticus* indicating depression in immune system of *H. diversicolor supertexta*.

The LC₅₀ of DO to *H. diversicolor supertexta* juveniles increased with exposure time. The tolerance of *H. diversicolor supertexta* juveniles to low DO decreased sharply by 13% and 41% after 84 and 96 h as compared with 72-h LC₅₀ at 25‰, and the tolerance of *H. diversicolor supertexta* juveniles to low DO decreased sharply by 15% and 28% after 84 and 96 h as compared with 72-h LC₅₀ at 35‰. Similar phenomenon was obtained previously in penaeid shrimps. Lin and Chen (2003) reported that the tolerance of *L. vannamei* juveniles to nitrite decreased by 11% and 35‰ after 48 and 96 h as compared with 24-h LC₅₀ at 25‰, and the tolerance of *L. vannamei* juveniles to nitrite decreased by 19% and 38% after 48 and 96 h as compared with 24-h LC₅₀ at 35‰.

In conclusion, the 72 and 96 h LC₅₀ of DO on *H. diversicolor supertexta* is 1.56 and 2.02 mg L⁻¹ at 25‰ and 1.43 and 1.83 mg L⁻¹ at 35‰, respectively. It appears that in the range of 25‰ and 35‰, the relationship between LC₅₀ of DO, salinity, and exposure time are $LC_{50} = 0.541 - 0.012S + 0.018T$ ($R^2 = 0.637$). The study has revealed that low DO concentrations might cause either lethality or depressed immune ability of abalone.

POPULATION CHARACTERISTICS AND CO-OCCURRENCE OF THREE EXPLOITED DECAPODS (*PANULIRUS ARGUS*, *P. GUTTATUS* and *MITHRAX SPINOSISSIMUS*) IN BOCAS DEL TORO, PANAMA

HECTOR M. GUZMAN¹* AND ALEXANDER TEWFIK²

¹Smithsonian Tropical Research Institute, Unit 0948, APO AA 34002, ²Department of Biology, McGill University, 1205 Ave. Dr. Penfield, Montreal, Canada, H3A 1B1

ABSTRACT Spiny lobster populations within the Bocas del Toro archipelago appear to be overexploited. Extensive visual surveys over a wide area of reef habitat down to 20 m in depth indicate mean lobster abundance, sizes, and percent maturity levels for both *Panulirus argus* and *P. guttatus* below other areas in the region. The almost complete absence of egg-bearing female lobsters may have serious implications for local production and recruitment and emphasizes the need for revision of management strategies for these populations, which are critical to the socio-economic wellbeing of local artisanal fishers and their dependent communities. An increase in the minimum carapace length for *P. argus* from 60–88 mm may allow protection for most juveniles. The implementation of a closed season or total fishing ban for lobster may also be considered to rebuild the spawning stock biomass to sustainable levels. The extensive pressure likely being exerted on lobster resources may spill over to co-occurring but poorly studied species, such as the large West Indian spider crab, *Mithrax spinosissimus*. This study presents the first data collected on a wild population of *M. spinosissimus*. More importantly, it illustrates the poor understanding we have of the inter-relationships between co-occurring species and the need to understand communities of populations that should be co-managed for the preservation of resources and biodiversity.

KEY WORDS: spiny lobster, *Panulirus*, spider crab, *Mithrax*, stock assessment, overfishing, Panama, shelter, dens

INTRODUCTION

The shallow water environments of the Panamanian coast provide important habitats for a wide variety of animal populations that support a number of important commercial and subsistence fisheries (Cruz 2000, Castillo & Lessios 2001, Guzman & Guevara 2002, Tewfik & Guzman 2003). Throughout these areas and the wider Caribbean region 3 large decapod crustaceans, *Panulirus argus* (Caribbean spiny lobster), *P. guttatus* (spotted spiny lobster), and *Mithrax spinosissimus* (West Indian spider crab) appear to coexist over reef habitats. Humans, to some lesser or greater extent, have attempted to exploit all three species with a particular focus on *P. argus* (Cochrane & Chakalall 2001). *P. guttatus* may be caught incidentally throughout the region but directed fisheries appear to exist only in Bermuda and Martinique (Evans & Lockwood 1994, Evans & Evans 1995). *M. spinosissimus* appears to have the most restricted use with incidental catches in some areas, namely the Panama Canal area, and limited efforts directed at experimental culture of the species (Wilber & Wilber 1991).

Our knowledge of the biology and ecology of these three organisms seems in approximate proportion to their level of exploitation. All three are nocturnal omnivores with varying diurnal den-dwelling preferences (Hazlett & Rittschof 1975, Lozano-Alvarez & Briones-Fourzan 2001). An extensive literature exists for the large *P. argus* and subsequently most lobster resource management in the Caribbean is based on experience with this species (Briones-Fourzan 1995). *P. argus* undergoes a number of ontogenetic habitat shifts, including the use of reef environments, and is highly migratory (Kanciruk & Herrinkind 1978, Butler & Herrinkind 1997). In contrast, the smaller *P. guttatus* appears to be an obligate, shallow-water reef dweller and is not migratory (Sutcliffe 1953, Sharp et al. 1997). Finally, very little is known about *M. spinosissimus* in the wild with limited observations being conducted in semi-natural and culture environments (Hazlett & Rittschof 1975, Wilber & Wilber 1991).

Given the significant role these decapods likely serve as intermediate consumers in reef and associated habitats and the socio-economic importance they have to local free-diving fishers, operating almost exclusively from small canoes (dugout cayucos), an extensive visual survey was conducted for these three species in the Panamanian archipelago of Bocas del Toro. The following paper is the first report of abundance, population structure, morphology, and spatial distribution of *P. argus* and *P. guttatus* in the study area. This work is also the first documented survey of a wild population of *M. spinosissimus* in the wider Caribbean.

MATERIAL AND METHODS

The survey was conducted over approximately 62,533 hectares of shallow water (<20 m) coral reef habitats in the Bocas del Toro archipelago between April and September 2002 (Fig. 1). A comprehensive description of the sea bottom topography, climate, geology, and reef distribution of the archipelago are available in several other publications (Rodriguez et al. 1993, Greb et al. 1996, Guzman & Guevara 1998). A total of 110 sites were randomly selected and surveyed. Within each site three replicate belt transects (100 × 6 m), randomly placed, were surveyed by two divers (3-meter width each) at four different depth strata (0–5 m, 5–10 m, 10–15 m, 15–20 m) when they occurred.

All individual lobsters encountered during the surveys were measured for carapace length (CL) and tail length (TL) to the nearest millimeter and sex was determined. Carapace length was measured from the base of the rostral horns to the posterior edge of the carapace and tail length was measured from the anterior edge of the tail to the posterior tip of the telson. Sex was determined by the presence of biramous pleopods for females and uniramous pleopods for males (Morgan 1980). The presence of a whole or remnant eggmass on the ventral abdominal segments was used to determine female maturity (Chubb 1994). All observed *M. spinosissimus* had carapace width (maximum distance between lateral margins) measured to the nearest millimeter as well as determination of sex again by the presence of biramous or uniramous pleopods. Maturity of females also was assessed based

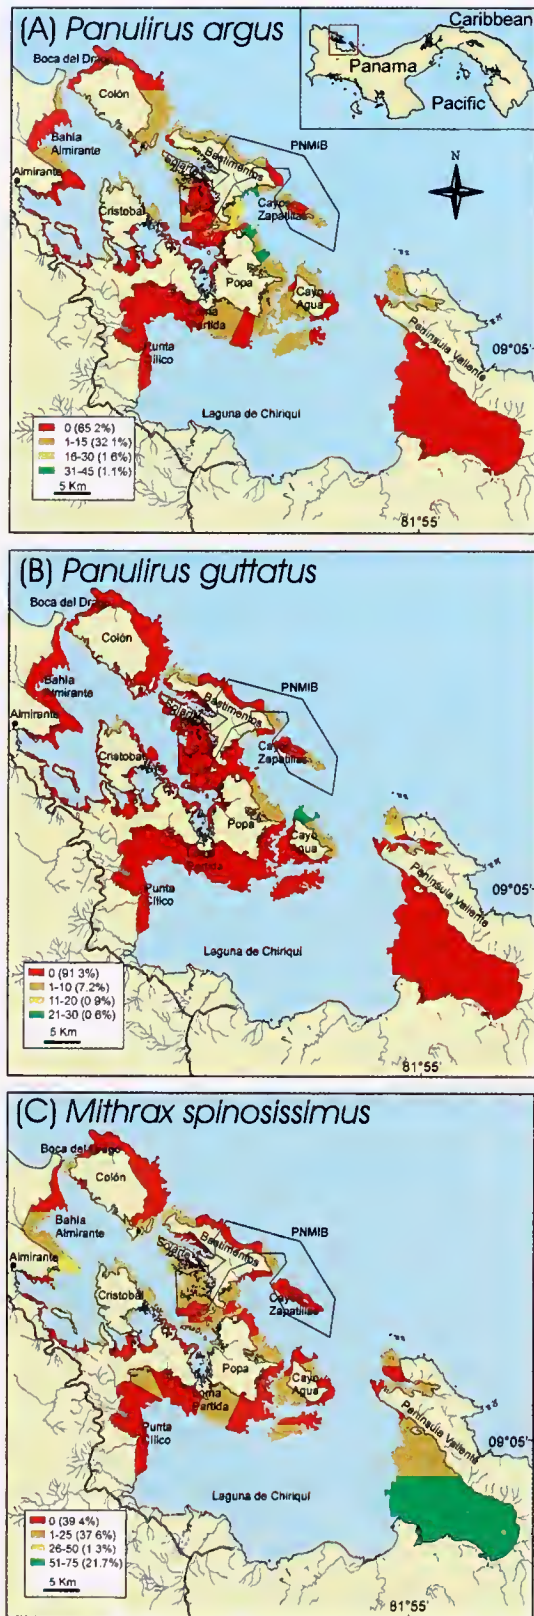

Figure 1. Location of the archipelago of Bocas del Toro in Panama (upper right). Density range distributions (individual ha⁻¹) of *Panulirus argus* (A), *P. guttatus* (B), and *Mithrax spinosissimus* (C) over shallow water reef habitats (<20 m).

on presence of a whole or remnant eggmass (Hernandez-Reyes et al. 2001).

The density distribution of all three species was calculated as mean number of individuals per hectare by site and depth strata. Site data was mapped using Geographical Information System (GIS). A digital classification for the area of study was based on topographic maps at scale 1:50,000. Density data were integrated using the programs MIP V3.1 (Map and Image Processing System) and ArcView V3.0. All data sets for morphologic correlations and abundance were analyzed using SYSTAT V10.2. Parametric techniques were used for correlations and non-parametric (Kruskal-Wallis one-way analysis of variance by ranks and the two-sample Kolmogorov-Smirnov test between pairs) techniques for differences in abundances between species and depth strata given the non-normal distribution of the data due to high numbers of zero values and the poor success of transforming such data.

RESULTS

A total of 496,800 m² (49.6 ha), using 828 transects, were surveyed down to 20 m during the course of the study. A total of 180 *Panulirus argus*, 41 *P. guttatus* and 189 *Mithrax spinosissimus* were found.

Highest densities for *P. argus* (31–45 lobster ha⁻¹) occurred at the North-east side of Popa and the southern edge of Bastimentos (see Fig. 1A). *P. guttatus* was most abundant (21–30 lobster ha⁻¹) at the northern tip of Cayo Agua, the southern edge of Bastimentos, and at the tip of the Peninsula Valiente (see Fig. 1B). All of these areas are associated with complex patch reef habitats. Maximum *M. spinosissimus* densities were found in areas of low visibility south of Peninsula Valiente (51–76 crab ha⁻¹) and at the southern tip of Bahía Almirante (26–50 crab ha⁻¹) (see Fig. 1C).

M. spinosissimus had the highest overall percent occurrence (55.5%) and *P. guttatus* the lowest (13.6%) with *P. argus* appearing at 50.0% of the 110 sites examined. The highest percent occurrence for each species by depth was; *P. argus*, 40.6% at 5–10 m; *P. guttatus*, 10.4% at 10–15 m; and *M. spinosissimus*, 34.0% at 5–10 m. The co-occurrence of species at sites was as follows: the 2 lobster species, 11.8%; *P. argus* and *M. spinosissimus*, 23.6%; *P. guttatus* and *M. spinosissimus*, 7.3%; and all 3 species, 6.4%. At no time was any individual den occupied by more than one species. None of the three species occurred in 22.7% of the sites.

Overall density values (mean individual ha⁻¹ ± SE) for the 3 decapod species, *P. argus*, 3.85 ± 0.66; *P. guttatus*, 0.91 ± 0.30; and *M. spinosissimus*, 4.11 ± 0.87, did vary significantly (Kruskal-Wallis, $H = 43.17$, $df = 2$, $P < 0.0001$). Both *P. argus* (Kolmogorov-Smirnov 2 sample differences, $P < 0.0001$) and *M. spinosissimus* ($P < 0.0001$) overall densities were higher than *P. guttatus*. Analysis of variance (Kruskal-Wallis) by depth revealed significant differences within the 0–5 m strata ($H = 29.55$, $df = 2$, $P < 0.0001$) and the 5–10 m strata ($H = 30.83$, $df = 2$, $P < 0.0001$) between *P. guttatus* and the other two species (Fig. 2). None of the three species individually varied significantly across the four depth strata. However, no *P. guttatus* were found below 15 m.

Carapace length (width for *M. spinosissimus*) frequency distributions were constructed for males and females and showed a unimodal distribution for all species over the range of individuals measured (Fig. 3). Carapace statistics (mean and standard error) for *P. argus*, *P. guttatus*, and *M. spinosissimus* were 52.0 mm ± 1.2 (±SE), 39.7 mm ± 1.6, and 91.7 mm ± 2.1 respectively. Significant correlations were made between CL and TL for both lobster spe-

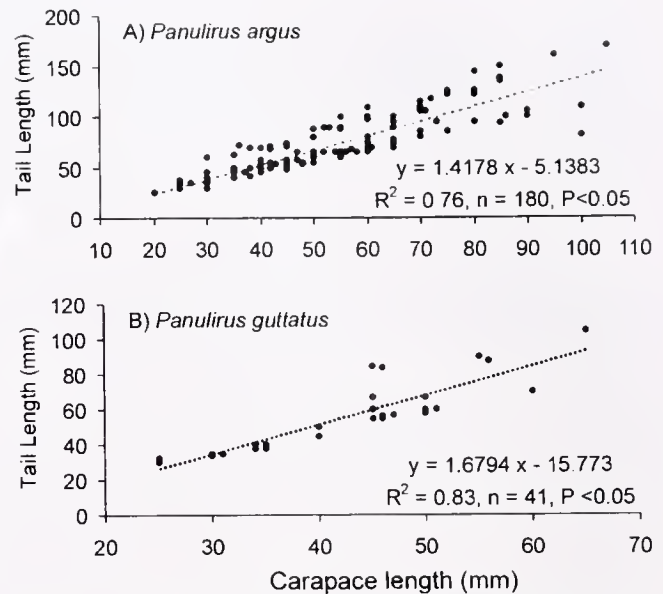

Figure 4. Tail length plotted against carapace length for female and male (A) *Panulirus argus* and (B) *Panulirus guttatus*, in Bocas del Toro, Panama.

found to be eggmass-bearing and only a single eggmass-bearing female *P. guttatus* (65-mm carapace) was encountered. The 50% maturity level for *M. spinosissimus* females, based on presence of eggmasses only, was found to be in the 81–90 mm carapace size class (Fig. 5).

DISCUSSION

The demand for spiny lobster resources throughout the Caribbean region over the last 50 years has resulted in depleted populations and an increase in the harvest of undersized and immature lobsters (King 1997, Cochrane & Chakalall 2001). This pattern may now be apparent in Panama with continual increases in landings (Fig. 6) and the documentation of removals of small lobsters in the San Blas archipelago (Castillo & Lessios 2001). This study may provide additional insights into depletions of *Panulirus argus* and *P. guttatus* populations in the Bocas del Toro through details on population abundance and distribution. This research also provides details on a poorly studied species, the West Indian spider crab (*Mithrax spinosissimus*), which may become a target of increased exploitation as a consequence of the depletion of other

Figure 5. Frequency distributions and percent maturity of female *Mithrax spinosissimus* ($n = 87$) in Bocas del Toro, Panama.

Figure 6. Total lobster landings (mt) and value (US\$ millions) of those landings in Panama (1996–2002). No detailed species composition is available (Cruz 2002).

more commercially preferred targets including lobster and conch (Tewfik & Guzman 2003) species.

The mean CL of both *P. argus* (52 mm) and *P. guttatus* (40 mm) are well below those reported in other areas of the Caribbean, including the San Blas archipelago (Yallondaro et al. 2001, Castillo & Lessios 2001, Losada-Tosteson et al. 2001). Even amongst fishery independent studies, the mean sizes in Bocas del Toro are small (Sharp et al. 1997, Tewfik et al. 1998). When examining size at sexual maturity and percent maturity of female lobsters, substantial depletions may be inferred when only a single egg-bearing *P. guttatus* (65 mm) was found in a total of 114 female lobsters examined of both species. Although our study was only conducted between April and September, it is generally considered that tropical species of *Panulirus* breed year around (Chubb 1994) with a significant proportion of egg-bearing females being identified over the period from February until November (Sharp et al. 1997, Castillo & Lessios 2001, Acosta & Robertson 2003). The small sizes and lack of mature individuals strongly suggest an over exploitation of the population as seen in other decapod fisheries (Abbe 2002). The importance of decreases in mean size and size at maturity is directly related to annual and lifetime egg production within a population (Pollock 1995) and ultimately levels of local recruitment. These links are known from other areas with simultaneous declines in spawning stock, recruitment, and individual size of adults (Lipcius & Stockhausen 2002). The skewed sex ratio towards males (1.6:1) in *P. guttatus* was as reported elsewhere (Sutcliffe 1953, Evans & Lockwood, 1994, Sharp et al. 1997, Losada-Tosteson et al. 2001). This skewness has been variably attributed to sex differences in survival, catchability, movement related to reproductive activity, and other behaviors (e.g., den guarding) and should be investigated further (Losada-Tosteson et al. 2001).

In contrast, morphological information obtained for *M. spinosissimus* including the large mean carapace width (92 mm) and high percentage of egg-bearing females, 45% with 50% maturity at approximately 85 mm, indicates that adults do exist. However, absolute comparisons of this *M. spinosissimus* population to others are difficult due to a shortage of other studies for this species in particular. Suggestions of a large literature base, and therefore understanding, on *Mithrax* spp. should be met with caution, as studies of the much larger *M. spinosissimus* are extremely limited.

Low overall density values for *P. argus* and *P. guttatus* compared with other fishery independent studies again suggest over-exploitation (Tewfik et al. 1998, Acosta & Robertson 2003). It is possible that *P. guttatus* was underestimated compared with *P. argus* due to its preference for dens that conceal the whole body and behaviors that include retreating back as far into the den as

possible to deter attacks from predators (Loranzo-Alvarez & Briones-Fourzan 2001). The absence of *P. guttatus* below 15 m conforms to the findings of other studies that this species is indeed a shallow water reef specialist (Sharp et al. 1997, Tewfik et al. 1998, Acosta & Robertson 2003). Absolute comparisons for *M. spinosissimus* are again impossible. The distribution of the three decapod species by depth (see Fig. 2) and area (see Fig. 1) are likely due to 2 main factors: resources and catchability. High densities may be facilitated by an abundance of shelter resources (complex reef habitats) or low catchability of targets due to low visibility for free-diving and/or rough surface conditions for the majority (87.5%) of fishers operating from small canoes. It is believed that a combination of both factors is responsible for the variability in density over the study area.

On the shelter resource, it is known that these three crustaceans do contend for occupancy of suitable den or crevice space. *P. argus* and *P. guttatus* may use the same dens, with *P. argus* on the floor and *P. guttatus* on the ceiling, but rarely simultaneously (Sharp et al. 1997). Observations of *P. argus* and *M. spinosissimus* indicate that the lobster can bar co-occupation by the crab but the crab cannot prevent the lobster from co-occupying a den (Hazlett & Rittschof 1975). The recruitment of juvenile *Panulirids* may also be limited by the availability of den or crevice space (Lipcius & Cobh 1994). Given the low densities of all three species and the observation that no more than one of the three species was seen occupying a single den it must be assumed that shelter resources are not limiting in Bocas del Toro at this time. However, the limitation of shelter resources among sympatric species in such systems may be of interest in the context of marine protected areas or fisheries reserves when ambient densities are increased through management.

In summary, it seems that the *Panulirid* populations of Bocas del Toro are in an overexploited state especially given the wide extent of the surveys throughout the archipelago. Recent interviews with the 192 lobster fishers within the area indicate that 55% are in favor of a ban on lobster with only 22% opposed. A further 18.5% would support a ban if other fishing possibilities existed (Cruz 2002). The strong support for management amongst resource users lends further credence to the view that lobsters are in short supply but also potentially bodes well for the rapid implementation of new protective legislation. Slight decreases in landings over the last 3 years within Bocas del Toro (18.63 mt in 1999, 17.95 mt in 2000, and 17.31 mt in 2001), in the context of national increases (see Fig. 6), may also reflect the difficulties that experienced fishers have locating lobsters.

A portion of Executive Decree No. 15 (March 30, 1981) describing size regulations for the harvest of lobster in Panama as a minimum CL of 60 mm and minimum TL of 120 mm seems inadequate and puzzling. Given the morphometric analyses conducted for *P. argus* in this study a 60-mm CL corresponds to an 80-mm TL. However, a 120-mm TL, by the same regression equation ($y = 1.4178x - 5.1383$), corresponds to an 88 mm CL. It seems obvious that a 60 mm minimum CL does not allow sufficient protection of juvenile *P. argus* because no mature individuals can be found at that size as well as the fact that the minimum CL and TL do not match. Furthermore, the average mean size of *P. argus* at maturity in the region ranges between 70–109 mm CL (Yallondaro et al. 2001). The existing minimum CL cannot be used for *P. guttatus* as virtually all individuals harvested would be illegal as is the case in Morrocoy National Park, Venezuela (Losada-Tosteson et al. 2001). It seems reasonable to raise the

minimum CL for *P. argus* to 88 mm to correspond to the existing and reasonable TL of 120 mm. This would allow many *P. argus* to become mature before being harvested and therefore increase the potential for contribution to future recruitment. Separate minimum sizes should be established for *P. guttatus* given their much smaller size. The suggestion that morphometric relationships established for either species in other parts of its range should be used for management is extremely dangerous and rejects the potential differences that may exist between populations. The exact minimum size for both lobster species should be based on more detailed local population CL when 50% of females are mature (egg-bearing) (Chubb 1994).

Further modifications to existing regulations could include a seasonal closure during reproductive peaks to allow undisturbed mating and spawning (Villegas et al. 1982). Alternatively, given the extremely low densities, a fishing ban could be implemented for several years to protect all lobsters allowing a rebuilding of the spawning stock, which presently seems to be low (Chiappone &

Sealy 2000, Goni et al. 2001). The exact nature of the management strategy for *M. spinosissimus* seems more difficult, given the extremely limited understanding we have of the species. The existence of mature crabs is a positive point. However, given the high pressure on many of the shallow-water marine resources of the archipelago further study is urgently required.

ABSTRACT *Aplysia dactylomela* is a large marine opisthobranch gastropod, which inhabits shallow tropical shoreline regions, eats red and green algae, and releases a purple ink when disturbed. Many functions have been proposed for this secretion and although there is no consensus on this, some of its constituents are believed to be derived from the red algal diet, it may provide the snail with a substantial survival advantage. *A. californica* only produces ink when it ingests red seaweeds. In some locations of the Northeastern Coast of Brazil, *A. dactylomela* is seen feeding only on green seaweeds, and yet it releases the ink. The aim of this work is to investigate this contradiction by studying the feeding habits of *A. dactylomela* and assessing the relationship between the algal diet and the purple ink. Feeding habits were investigated by field observation and by analysis of gut contents. Purple ink production was monitored by histologic analysis of the ink gland from sea hares kept in water tanks, fed with either red or green seaweeds. Composition and protein profile of the purple ink also were studied. Homologies between seaweed components and the purple ink were sought for by immunodiffusion techniques. Our findings are that the sea hare *A. dactylomela*, likewise other *Aplysia* species, needs to consume red seaweeds to be able to secrete the purple ink. The proteins of the ink seem to be synthesized by the sea hare itself and are not obtained directly from the diet, as is the case for the ink pigments.

KEY WORDS: *Aplysia dactylomela*, purple ink, ink gland, seaweed diet

INTRODUCTION

Aplysia dactylomela is a large marine opisthobranch gastropod which inhabits shallow tropical shoreline regions, eats red and green algae, and lays large numbers of fertilized eggs in string-like gelatinous masses close to the sea surface. It is hermaphroditic and nocturnally active, but may be exposed to sunlight as it rests during the day (Carefoot 1987). Sea hares probably are best known because of the purple ink they release when disturbed. This ink is secreted from the ink gland located on the edge of the mantle shelf, and the ability to produce purple ink is reported to be associated with a red seaweed-containing diet (Coelho et al. 1998). Of the 37 species of sea hare from the *Aplysia* genus, 30 can secrete purple ink (Nolen et al. 1995). Many functions have been proposed for this secretion, such as camouflage, alarm signal, pheromone, aposematism (use of color patterns by prey animals to signal their distastefulness to predators), bile excretion, predator deterrent, and cue of danger (Johnson & Willows 1999). Probably the ink has more than one role in the biology of sea hares. Although there is no consensus on the biologic function of the ink, it is known that some of its constituents are derived from red algae in the diet (Prince et al. 1998), and it provides the snail with a substantial survival advantage. Recent work by Prince et al. (1998) on the ink glands of *A. californica* has improved our understanding of ink gland structure and processing and secretion of purple ink.

In addition to studies of the ecologic and biologic aspects of chemical defense in sea hares, special attention also has been paid to the isolation and characterization of new bioactive substances from the purple ink. Thus, many bioactive substances have been isolated from the purple ink, including proteins with antibacterial

activity in *A. punctata* (Nistratova et al. 1992), antitumor and cytolytic activities in *Dolabella auricularia*, (Kisugi et al. 1989, Yamazaki et al. 1989a) and cytolytic and antibacterial activities in *A. kurodai* (Yamazaki et al. 1989b, Yamazaki et al. 1990). In Brazil, antibacterial and hemagglutinating activities were described for the purple ink of *A. dactylomela* (Melo et al. 1998; Melo et al. 2000).

On the northeastern Coast of Brazil, there is an abundance of seaweed species that support the great biodiversity of this tropical region. On some beaches there is a predominance of green seaweeds (mainly *Ulva fasciata*), whilst on others, red seaweeds prevail. On the beaches dominated by green seaweed, *A. dactylomela* is seen feeding mainly on them and yet releases the purple ink when disturbed. This fact could be intriguing, considering that other *Aplysia* species need to consume red seaweeds to be able to produce the ink. To solve this apparent contradiction this study investigates the feeding habits of *A. dactylomela* and assesses the relationship between the algal diet and the purple ink.

MATERIALS AND METHODS

Determination of Feeding Habits

Feeding habits of *A. dactylomela* were observed in 2 beaches of Ceará State, Northeast of Brazil, between August 2000 and July 2001. One beach was particularly rich in the green seaweed *Ulva fasciata* (beach 1, 38°38'48"W and 3°41'24"S); whereas, the other was densely rich in the red species, particularly *Hypnea musciformis* and *Gracilaria* spp. (beach 2, 39°25'45"W and 3°22'18"S). Feeding habits of sea hare were examined monthly during daytime at low tide by observing the seaweed species consumed in the field

*Corresponding author. E-mail: vmmelo@ufc.br

and by dissecting under a stereomicroscope the gut contents of the sea hares and capturing the images with a digital camera (Sony-Mavica, Japan).

Histologic Analysis of the Ink Gland

Specimens of *A. dactylomela* were collected during low tide and transported to the laboratory in a container with seawater. Some specimens were de-inked by squeezing them gently for a few minutes outside the water and then kept in seawater tanks for 15 days with unialgal diets (*U. fasciata* or *Gracilaria* sp.) to observe whether there was purple ink production. At the end of this period, sea hares were anaesthetized by storage in a refrigerator and then dissected carefully to remove the ink gland.

For light microscopy, ink gland samples were fixed with Bouin mixture (saturated picric acid solution, 40% formaldehyde, glacial acetic acid (15: 5:1 v/v) and embedded in paraffin. Tissue sections (5 μ m) were stained with hematoxylin and eosin (Junqueira & Junqueira, 1983) and with bromophenol blue for detection of proteins (Pearse 1960). Histologic sections were observed under a microscope, and photographs were taken.

Chemical Composition of Purple Ink

Purple ink was analyzed for contents of water, protein (total nitrogen), reduced carbohydrate, lipid, and ash. For the water determination, 1g of ink was dehydrated in an oven at 100°C to 110°C to constant weight. Total nitrogen was determined in samples of freeze-dried purple ink by micro-Kjeldahl digestion (Baethgen & Alley 1989). The content of reduced carbohydrate was determined according to Dubois et al. (1956). Lipid content was determined by n-hexane Soxhlet extraction, and ash was quantified by heating 1g of ink in a muffle furnace at 620°C for 18 h.

Amino Acid Analysis

Dry purple ink (1 mg) was hydrolyzed in 1 mL 6 M HCl with 1% phenol (w/v), in a sealed glass tube under N₂, at 110°C for 22 h. After hydrolysis, HCl and phenol were removed by evaporation, and the residue was analyzed in a Biochrom 20 (Pharmacia-LKB) amino acid analyzer.

Electrophoretic Profile of Ink Proteins

Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) was performed in the presence of beta-mercaptoethanol according to the method of Laemmli (1970). Proteins were stained with silver nitrate (Blum et al. 1987). Bovine serum albumin (66.0 kDa), egg albumin (45.0 kDa), porcine pepsin (34.7 kDa), bovine β -lactoglobulin (18.4 kDa), and egg lysozyme (14.3 kDa) were used as standards (Sigma Co., USA).

Seaweed Protein Extraction and Determination

Proteins were extracted from fresh samples of the green seaweed *U. fasciata* and the red species *H. musciformis* and *Gracilaria* sp. The samples were ground with a mortar and pestle with the following buffers at 50 mM: Glycine-HCl, pH 2.6; Tris-HCl, pH 7.0; and sodium borate, pH 9.0. The extracts of *U. fasciata* and *H. musciformis* were prepared at the proportion of 1:3 (m/v) and that of *Gracilaria* sp. at 1:5 (m/v). The extracts were filtered through a nylon tissue and centrifuged at 15,000 g for 10 min at 4°C. The supernatants (crude extracts) had the protein content determined according to Bradford (1976) with bovine serum albumin (BSA) as the standard (purchased from Sigma Co., USA).

Anti-Purple Ink Polyclonal Antibody

Anti-purple ink polyclonal antibody was developed in a 3-month-old albino rabbit, which was immunized by intramuscular injection with 1 mg of purple ink, previously dialyzed and freeze-dried and then dissolved in 1 mL of sterile saline solution containing incomplete Freund adjuvant, 1:1 v/v (Sigma Co.). Booster injections were given without adjuvant subcutaneously on the 14th, 21st, 28th, and 35th days after the primary injection. Immune serum was obtained by blood sampling from the marginal ear vein on the 21st, 28th, and 35th days.

Immunodiffusion Assay

Immunologic relationships between protein extracts from seaweeds and the purple ink were assessed by the Ouchterlony double diffusion method (Hudson & Hay 1989). The assays were done in 1% agar plates prepared with 20 mM sodium phosphate buffer, pH 7.0, containing 150 mM NaCl and 0.02% sodium azide. After solidification of the agar, wells were made with a Pasteur pipette, and 30 μ L of each seaweed extract was applied into each well and tested against the anti-purple ink antibodies applied in the central well. After incubation at room temperature for 48 hours, the gels were washed with 150 mM NaCl, dried, and stained with Coomassie brilliant blue for visualization of the precipitation arcs.

RESULTS

Feeding Habits

Sea hares from beach 1 were frequently surrounded by the green alga *U. fasciata*, and to a much less extent by red alga species (*Gracilaria* spp. and *H. musciformis*). In beach 2, however, the snails were surrounded by red algae, mainly *H. musciformis*, and some brown species. The analysis of gut contents from specimens collected showed that the snails ate mainly those alga species surrounding them. Those from beach 1 had gut contents comprised of approximately 70% *U. fasciata* (and traces of red species); whereas, those from beach 2 contained over 90% *H. musciformis* (photography not included).

Figure 1. Light micrographs of ink glands in red-seaweed-fed (A) and green-seaweed-fed *Aplysia dactylomela* (B). Vesicles (v) were full of ink (i) in red-seaweed-fed sea hares and empty in green-seaweed-fed. Scale bars: A, B, 100 μ m.

TABLE 1.

Chemical analysis of the purple ink from *Aplysia dactylomela*.

Components	% Dry Basis
Total protein (N \times 6.25)	64.87 \pm 2.56
Reduced carbohydrate	9.07 \pm 1.84
Lipid	2.20 \pm 0.40
Ash	2.72 \pm 0.20

Values are means \pm standard deviation of at least triplicate analyses.*Histologic Analysis of the Ink Gland*

Histologic analysis showed that ink gland tissues from animals whose gut contained mainly green algae had most vesicles empty. The same was observed with the animals kept on the *U. fasciata* diet in the laboratory tank. By contrast, the ink glands of animals from beach 2, which consumed mainly red alga species, had most vesicles full (Fig. 1).

Chemical Composition of Purple Ink

The purple ink is composed of approximately 99.5% water. Purple ink proximal chemical analysis, on dry basis, is described in Table 1, being comprised mainly of proteins (over 60%). Regardless of diet, the ink had the same basic composition of protein, carbohydrate, lipid, and ash.

Amino Acid Composition

The results of amino acid composition (Table 2) showed that the purple ink contains high levels of acidic amino acids, glutamic, and aspartic acid and very low content of sulfur amino acids.

Electrophoretic Profile of Ink Proteins

The purple ink of sea hares from beaches 1 and 2 showed similar electrophoretic profiles in terms of mobility and intensity

TABLE 2.

of protein bands (Fig. 2). Two prominent bands were observed at 60 and 45 kDa, several minor bands span the apparent molecular mass range 20–30 kDa, whilst others were approximately 15 and few below 14 kDa.

Serological Relationship Between the Purple Ink and Seaweed Extracts

The immunodiffusion assay showed that the anti-purple ink antibodies reacted with the ink but did not recognize any seaweed component extracted either with acid, neutral or alkaline buffer (photography not included). This indicates, therefore, that no immunologic reactivity exists between components of algal diet and the purple ink.

DISCUSSION

This study describes the relationship between the seaweeds consumed by the sea hare *A. dactylomela* and its purple ink.

Although it has been reported that the secretion of purple ink by sea hares is associated with their consumption of red seaweeds (Prince et al. 1998), specimens that consumed mainly green seaweeds (beach 1) also were seen to release the purple ink. This contradiction was solved when the analysis of gut contents showed the presence of traces of red seaweeds, indicating that minor consumption of red species was enough to support the ink production.

Figure 2. SDS-Polyacrylamide gel electrophoresis. Lanes 1 and 3, molecular mass markers; lane 2 purple ink from *Aplysia dactylomela* collected at beach 1 (green seaweed rich) and lane 4 purple ink from specimens from beach 2 (red seaweed rich).

To prove that *A. dactylomela*, like *A. californica* (Prince et al. 1998; Coelho et al. 1998), only produces ink when it ingests red seaweeds; laboratory experiments were conducted with sea hares receiving the green seaweed *U. fasciata*, or the red *Gracilaria* sp., as the sole source of food. Our light microscopy studies of the ink gland of sea hares consuming only *U. fasciata* showed that most of the vesicles were devoid of purple ink; whereas, individuals that consumed red seaweeds had full vesicles in the ink gland. These observations confirm the necessity of red-seaweed consumption for *A. dactylomela*, and probably other sea hares of the same genus, to be able to secrete the purple ink.

The chemical analysis of the purple ink showed that, regardless of the main seaweed species consumed by the sea hare, the content of protein in the ink was the same. This could indicate that either diet, rich in green or red seaweeds, must be able to supply the amino acids necessary for ink protein synthesis. Our analysis of amino acid composition showed that the purple ink is rich in acidic amino acids and has very low content of sulfur amino acids, reflecting the amino acid composition of both seaweeds (Ramos et al. 2000). Likewise, the electrophoretic profile of the ink proteins was always the same, regardless of the sample origin (beach 1 or 2), time of the year, or sea hare age. The finding that the anti-ink antiserum did not recognize any protein of the seaweed extracts suggests that the sea hare itself synthesizes the ink proteins and that they are not obtained directly from the diet, as is the case for

the ink pigments (Troxler et al. 1981; MacColl et al. 1990). Coelho et al. (1998) previously suggested that the pigment of *A. californica* purple ink is of algal origin, but the proteins are not. Thus, there seems to be no doubt about the origin of the ink substances (pigments and proteins) in *A. dactylomela*. Nevertheless, the roles in the purple ink have not yet been completely elucidated. Several biologic activities have been described *in vitro* for isolated proteins (Kisugi et al. 1989; Yamazaki et al. 1989a; Yamazaki et al. 1989b; Yamazaki et al. 1990; Nistratova et al. 1992; Melo et al. 1998; Melo et al. 2000) and pigments (Wessels et al. 2000) from sea hare ink, and all give support to a defense role.

CONCLUSIONS

The sea hare *A. dactylomela*, and possibly other *Aplysia* species, needs to consume red seaweeds to be able to secrete the purple ink. The pigment is from algal origin; whereas, the proteins are not. The protein content and composition seem to be always the same, regardless of the seaweed species consumed.

NUCLEIC ACID DERIVED INDICES OR INSTANTANEOUS GROWTH RATE AS TOOLS TO DETERMINE DIFFERENT NUTRITIONAL CONDITION IN CUTTLEFISH (*SEPIA OFFICINALIS*, LINNAEUS 1758) HATCHLINGS

ANTÓNIO V. SYKES,* PEDRO M. DOMINGUES AND JOSÉ P. ANDRADE

C.C. MAR Universidade do Algarve F.C.M.A., Campus de Gambelas 8000, 817 Faro, Portugal

ABSTRACT Two groups of 100 cuttlefish hatchlings each were used to determine the duration of the yolk reserves, during which growth can be obtained with no food supply. One group was fed live grass shrimp *ad libitum* from the 3rd day of life onwards, while the other was starved during the whole experiment. The experiment lasted 7 days, because this was the 1st day where a negative growth rate was obtained. Nucleic acid derived indices and instantaneous growth rates (IGR) were used as a way to describe their condition, when all the yolk reserves would be exhausted and to determine the most accurate tool to express growth and condition. RNA/DNA ratios described clearly the differences ($P < 0.05$) between fed and starved hatchlings cultured at $23 \pm 2^\circ\text{C}$, especially from day 4 onwards. Correlation between IGR and RNA/DNA ratios was only attained for the starved population ($R = 0.90$; $P = 0.0374$). DNA concentration was identical ($P > 0.05$) between groups and did not display a clear pattern with increasing age. Correlation between IGR and DNA was only attained for the fed population ($R = -0.90$; $P = 0.0374$). RNA concentration values were different from day 5 onwards. Any of the nucleic acid derived indexes were not accurate enough to express growth and condition, so IGR seems to be the most accurate and inexpensive way to describe hatchlings growth and condition in controlled conditions.

INTRODUCTION

When culturing any species in intensive aquaculture, time of first feeding is of extreme importance. Food should be available when larvae or hatchlings are finishing the absorption of the inner yolk reserves and starting to feed externally. Cuttlefish are known to be voracious feeders throughout their life cycle and accept a wide range of prey (Guerra 1985, Castro & Guerra 1989, Pinzon du Sel & Daguzan 1992, Domingues et al. 2001a, Domingues et al. 2003). Some authors (Wells 1958, Richard 1971, Richard 1975, Boletzky 1983, Boletzky 1987, and Nixon 1985) have studied the embryonic development and the early life history of cuttlefish and set the end of the inner yolk reserves around the 3rd day of life. However, according to Domingues et al. (2001b), cuttlefish in unfed or poor nutritional condition (as result of prey with poor nutritional profile) can last as much as 20 days. The only way to determine optimal timetables for first feeding, thus optimizing cuttlefish production, is the use of condition analysis. Condition is a measure of the physical status or well being of an animal and may be used to evaluate growth or survival rates (Bolger & Conolly 1989, Ferron & Leggett 1994).

Nutritional condition of larval stages plays an important role in the knowledge of the recruitment of marine species. Nutritional condition of fish larvae can be evaluated using several methods: morphometric, histologic, and biochemical (Chícharo 1993). However, costs and results associated with each methodology are not similar between them. So, the main questions are which methodology to choose when trying to evaluate the condition of the animal, and the compromise between costs and accuracy of results to achieve. The use of morphometric methodologies are standards in most aquaculture and fishery laboratories around the world. Nowadays, biochemical methodologies related to nucleic acid derived indices are becoming standards also.

One of the most commonly used methods for determining the nutritional condition and growth is the RNA/DNA ratio (Buckley 1979, Buckley 1980, Buckley & Lough 1987, Clemmesen 1988,

Clemmesen 1990, Robinson & Ware 1988). The use of this methodology is based on the assumption that DNA is present in constant concentrations, under changing environmental conditions or during starvation (Richard et al. 1991), whereas RNA varies, decreasing in starving animals (Buckley 1984, Buckley & Lough 1987). According to Bulow (1987), RNA concentrations are higher in tissues with faster growth rates or with a higher rate of protein synthesis. The RNA/DNA ratio indicates quantities/concentrations of RNA per cell and is the most accurate when estimating tecidular proteosynthetic activity (Bulow 1987, Buckley 1981, Buckley 1984). The use of RNA concentration in a tissue as an indicator of growth is based on the assumption that RNA is related to the potential for protein synthesis (Houlihan 1991). However, large variation in the RNA/DNA ratio may occur in fed larvae (Clemmesen 1988, Raae et al. 1988). Recent studies suggest that the RNA/DNA ratio is one of the best indicators of the nutritional condition of several marine organisms (Clemmesen 1994, Bailey et al. 1995, Chícharo 1997, Chícharo et al. 1998, Chícharo et al. 2001).

Biochemical methodologies have been proposed to evaluate condition in post-hatch and juvenile cuttlefish (Clarke et al. 1989, Pierce et al. 1999, Koueta et al. 2000). One of those is the RNA/DNA nutritional condition ratio. However, until now, only RNA concentrations in the muscle were shown to be directly correlated with growth in *Octopus vulgaris* (Houlihan et al. 1990) and *Sepia officinalis* (Castro & Lee 1994).

The objective of this research is to determine: (1) how long cuttlefish hatchlings could survive on inner yolk reserves after hatching, using nucleic acid derived indices (RNA/DNA ratio, [DNA]/g and [RNA]/g) and instantaneous growth rates (IGR) as ways to describe their growth and condition and (2) the best descriptor for condition, based on a compromise of money spent, results achieved, and when to apply it.

MATERIAL & METHODS

Experimental Conditions

A group of 100 cuttlefish hatchlings was used to determine the maximum starvation period, while another group of 100 hatchlings

*Corresponding author. E-mail: asykes@ualg.pt

(control) were fed live grass shrimp (*Palaemonetes varians*) captured from nature. The control group was fed ad libitum from day 3 to 7. Both groups were placed in baskets (5.4 L water volume, 1-mm mesh) which were in 250 L tanks of a flow-through system with a UV unit, described in Domingues et al. (2001b and 2002). Water flow was of 12 L/h. Water temperature was of $23^{\circ}\text{C} \pm 2^{\circ}\text{C}$ and salinity was of 37 ± 2 PSU; lights were running on a 12 h per day basis. This system ensured an excellent water quality, necessary for hatchling culture.

Because several authors reported that cuttlefish hatchlings start external feeding on the 3rd day of life (Richard 1971, Richard 1975, Boletzky 1983), this was the starting period for collection of data on growth, survival, and condition. However, two samples of 20 newly born hatchlings were taken to determine RNA and DNA concentrations and ratio at time of hatching. The experiment lasted until the 7th day, because, at this time, negative growth rates for the starved animals started to be obtained. Each day 20 hatchlings were collected from each group, weighed, frozen, and stored (at -80°C) for later nutritional condition analysis. Collected data were used to calculate: (1) mean weight; (2) mean instantaneous growth rate (IGR) ($\%\text{BW}\cdot\text{d}^{-1}$) = $(\ln W_2 - \ln W_1)/t \times 100$, where W_2 and W_1 are the final and initial weight respectively, \ln the natural logarithm and t the number of days of the time period; and (3) survival rates.

Nucleic Acid Determinations

Methods for the determination of nutritional condition were adapted from Esteves et al. (2000) and Chicharro et al. (2001).

Purification of tissues was achieved by homogenizing each cuttlefish in 2.5 ml TRIS-HCl solution for 5 sec with an ultraturrax unit (IKA Labortechnik), and 10 sec in an ultrasonic homogenizer unit (4710 Series, Cole Parmer Instruments Co.). This methodology was applied to obtain maximum homogeneity of tissues and disruption of cells, as well as a total destruction of the cuttlebone. After that, the homogenate was washed with 50 μl 3% sarcosine Tris-HCl and 1.35 mL Tris-HCl (Trizma, pH = 8) solutions and centrifuged during 5 min, at 9860 RPM and 4°C . Subsequent fluorescence-photometric measurements were done. DNA+RNA measurements were done combining 0.2 mL of supernatant with 0.4 mL of Tris-NaCl (Trizma, pH = 7.5) and 0.05 mL ethidium bromide (EB) (0.1 mg/mL), which is a nucleic fluorochrome dye specifically designed. DNA measurements were done combining 0.2 mL of supernatant with 0.35 mL of Tris-NaCl (Trizma, pH = 7.5) and 0.05 mL of ribonuclease A (Type-II A, Sigma, 0.12 $\mu\text{g}\cdot\text{mL}^{-1}$). After that, this mixture was incubated in a water bath for 30 min at 37°C and allowed to reach room temperature for 20 min. Same quantities of ethidium bromide (EB) (0.1 mg/mL) were then used to stain the DNA and DNA+RNA in mixture samples. Each cuttlefish sample was analyzed in triplicate. Values of DNA and RNA were then estimated calculating the mean value of the 3 replicates.

Determinations of nucleic acid concentration were identical for both DNA+RNA and DNA measurements. The fluorescence due to total RNA was then calculated using the difference between total fluorescence (RNA+DNA) and the fluorescence after the application of ribonuclease A. This second fluorescence is assumed to be due to DNA, after the subtraction of the self-fluorescence by the enzyme. Both fluorescences were determined by exciting at 365 nm and reading at 590 nm with a Hitachi spectrofluorometer (model 650-10). Concentrations of both DNA and RNA were de-

termined using standard curves of known concentrations of calf DNA and yeast RNA, after carrying out the same methodology as for the samples.

Data Analysis

Mann-Whitney tests (Zar 1984) were used to determine differences in IGR, RNA/DNA, [DNA]/g larvae and [RNA]/g larvae between fed and unfed hatchlings. Spearman rank order correlation tests (Zar 1984) were used to determine correlations between IGRs and RNA/DNA and IGR and DNA of fed and unfed hatchlings.

RESULTS

IGR and Survival

Both starved and fed cuttlefish hatchlings showed different IGRs ($P < 0.05$) (Fig. 1). Starved cuttlefish group showed a steady decline in IGR from values of about $6\% \text{ BW}\cdot\text{d}^{-1}$ (day 4) to negative values of approximately $-1.4\% \text{ BW}\cdot\text{d}^{-1}$ (day 7). Fed hatchlings showed similar values of IGR (minimum of 3.6% and maximum of $8.4\% \text{ BW}\cdot\text{d}^{-1}$) to the ones obtained by Sykes (2003).

Mortality was low and only 6 out of 100 hatchlings (6%) died in each group being tested.

Nucleic Acid Derived Indices

Standard calibration curves were obtained for both DNA and RNA. DNA calibration can be described using linear regression analysis by the equation $y = 13.961 \times + 3.7498$ ($r^2 = 0.996$; $n = 588$). RNA calibration can be described using linear regression analysis by the equation $y = 4.3829 \times + 3.9095$ ($r^2 = 0.992$; $n = 315$).

Hatchling condition was significantly different between fed and unfed hatchlings ($P < 0.05$). RNA/DNA ratio of fed hatchlings increased, whereas in starved hatchlings decreased, throughout the experiment (Fig. 2). Maximum values of RNA/DNA ratio (1.60 at day 7) were obtained in fed hatchlings whereas minimum values (0.00 at day 7) were obtained in starved hatchlings. Standard deviation of RNA/DNA ratio was high for both groups.

DNA concentration per g of body weight showed no significant differences ($P > 0.05$) between concentrations until day 4, whereas during day 5 to day 7, DNA concentrations were significantly different ($P < 0.05$) between both groups (Fig. 3). DNA concentration was higher in starved than in fed hatchlings. Maximum values were obtained in starved hatchlings ($13.04 \mu\text{g/g}$ at day 5) whereas minimum values were obtained in fed hatchlings (5.23

Figure 1. Growth rates of starved and fed hatchlings.

Figure 2. RNA/DNA ratios of starved and fed hatchlings. Vertical lines represent standard deviations.

$\mu\text{g/g}$ at day 7). Standard deviation was higher in starved than in fed hatchlings.

RNA concentration per g of body weight showed no significant differences ($P > 0.05$) in concentrations only for day 4 and 5 (Fig. 4). RNA concentration was higher in fed than in starved hatchlings. Maximum values were obtained in fed hatchlings ($9.05 \mu\text{g/g}$ at day 5) whereas minimum values were obtained in starved hatchlings ($0.00 \mu\text{g/g}$ at day 7). Standard deviation was high in both groups.

Spearman rank order correlation showed correlation between IGR and RNA/DNA for the starved group ($R = 0.90$; $P = 0.0374$), but it did not show correlation for the group fed with grass shrimp ($R = 0.80$; $P = 0.1041$) (Fig. 5 and Fig. 6). IGR and RNA/DNA decreased with increasing age for the starved group while the opposite occurred for the fed group.

Correlation of IGR and DNA for both fed and unfed hatchlings using Spearman rank order correlation showed inconclusive results. Results of the correlation between IGR and DNA for the fed group were significant ($R = -0.90$; $P = 0.0374$) whereas the correlation for IGR and DNA of the unfed group were not significant ($R = -0.30$; $P = 0.6238$).

DISCUSSION

According to Berrigan and Charnov (1994), both low temperature and below normal feeding rates will reduce growth rates in most ectotherms. Forsythe et al. (1991) stated that temperature and

Figure 4. [RNA]/g of larvae of starved and fed hatchlings. Vertical lines represent standard deviations.

ration levels are the main factors determining variations in cephalopod growth rates. Because temperature was the same for both groups, differences in growth were directly related to feeding or starving.

Fed cuttlefish hatchlings readily accepted grass shrimp from the 1st day of feeding (day 3) onwards. Results obtained lead us to believe that inner yolk reserves should last at least to the 4th day after hatching, at a temperature of $23^\circ\text{C} \pm 2^\circ\text{C}$. This assumption is made based upon the decline in both patterns of IGR and RNA/DNA ratios for fed hatchlings on the 4th day, and the fast decline in starved hatchlings from the 5th day onwards. However, time for the first feeding should be established for the 3rd day after hatching because of cuttlefish energy consumption when capturing grass shrimp. If hatchlings are first fed later than this 3rd day, it will probably originate higher mortality values at this optimal culture temperature, because their capability to capture grass shrimp will be greatly diminished by lack of energy resources. This lack of energy resources is supposed to be related to the ending of the inner yolk reserves and their metabolization. The establishment of a time for the first feeding is particularly important because cuttlefish eggs do not usually hatch in the same day as fish do, but instead, they take their time hatching. This problem is caused by females intermittent spawning (Boletzky 1987b).

Previous studies showed that growth rates have been the most accurate way of measuring cuttlefish growth and condition for the first weeks of life. Instantaneous growth rates have been calculated for a number of cephalopods (Forsythe 1993, Lee 1994, Sykes 2003) and can give some indication about cuttlefish condition over time. Unfed or underfed animals will display negative or very slight variations in IGR during survey time, respectively. On the other hand, well-fed animals will display positive IGR. In the present experiment, fed and starved hatchlings showed these patterns.

Clarke et al. (1989) reported that in juvenile cuttlefish the RNA/DNA ratio was positively correlated with growth in individuals kept at 17.5°C , but no correlation was found on those kept at 12°C . According to the same author, RNA/DNA ratios of cuttlefish with low growth rates were similar to those reported for fish larvae; nucleic acid ratios at higher growth rates were higher than those reported so far. These authors also stated that higher values of RNA/DNA ratio could be related to the very high growth rates of cephalopods. In the present study, RNA/DNA ratios clearly described the differences between fed and starved hatchlings cul-

Figure 3. [DNA]/g of larvae of starved and fed hatchlings. Vertical lines represent standard deviations.

Figure 5. RNA/DNA ratios and IGR for starved hatchlings.

tured at $23 \pm 2^\circ\text{C}$, especially from day 4 onwards. However, RNA/DNA ratio results obtained in the present work were similar to those reported for fish larvae, and not higher as expected. This is particularly important because at this temperature cuttlefish will grow exponentially, as reported by Lee (1994) and more recently by Domingues et al. (2001a, 2002) and Sykes (2003). It seems that although feeding and growth rates are extremely high at this time of their life cycle, a correlation between growth and condition cannot be achieved. In fact, for the present study, when trying to establish a correlation between IGR and RNA/DNA ratios for both fed and starved groups, results were not conclusive. Although the present results showed a similar pattern, a statistical correlation was only observed for the starved group. According to Clarke

et al. (1989), if the RNA/DNA ratio is to be used as a tool in ecologic studies, there is a need for this relationship of RNA/DNA ratio with the nutritional status and growth rates to be precise. The same authors also add that RNA/DNA ratios would only allow distinction between zero, average and maximal growth. Castro & Lee (1994) stated that RNA/DNA ratio might not always be the best growth indicator for *S. officinalis*. So, RNA/DNA ratios are not accurate enough for determination of cuttlefish condition, but they will allow distinction between starved and fed animals.

These results indicate that DNA concentration should be of great importance when describing nutritional condition of cuttlefish hatchlings rather than RNA/DNA ratios. DNA concentration

Figure 6. RNA/DNA ratios and IGR for fed hatchlings.

seems to be inversely correlated with IGR. Higher values of DNA were obtained when IGR displayed the lower values. Clarke et al. (1989) reported that the percentage of DNA/dry weight was much more stable in fed larvae than the RNA/DNA ratio. Chicharo (1993) stated that DNA concentration of fish larvae was especially sensitive to starving conditions after complete depletion of yolk reserves. It seems that the same happens with cuttlefish hatchlings. Bergeron and Person Le-Ruyet (1997) suggested that DNA concentration per g of body weight would be a better and simpler index of larval nutritional status than the RNA/DNA ratios, because it was more stable in fed hatchlings, and the methodology used to measure DNA alone would be easier, more sensitive, and less expensive than RNA/DNA ratios. However, correlation between IGR and DNA was only statistical significant for the fed group, and so DNA concentration is also not accurate enough to describe growth in cuttlefish.

Values obtained for RNA concentration in this study should describe starved hatchling condition and minimum or non-existent rate of protein synthesis, at $23\text{ C} \pm 2\text{ C}$. Mathers et al. (1994) found that an increase in protein content in fish larvae was not associated with similar increase in RNA concentration. According to Pierce et al. (1999) there is no direct relation between RNA concentration and growth rates in cephalopod species like *Loligo forbesi*, *Eledone cirrhosa* and *Octopus vulgaris*. The work of Castro and Lee (1994) showed, however, that the RNA contents in mantle muscle could be used as short-term indicator of instantaneous growth rate and condition of cuttlefish. More recently, Koueta et al. (2000) found that changes in RNA content of muscle were related to growth in *S. officinalis* hatchlings. The same author also stated that RNA content of the muscle increased significantly between underfed (low ration) and maintenance fed (medium ration) groups and were according to Bulow's (1987) findings for fish. Results from this study fall within the condition results obtained by Castro and Lee (1994) and Koueta et al. (2000), with a clear distinction between fed and starved animals. However, they are once again not accurate enough to describe growth because, in the present study, RNA concentration had great variations between animals that were under the same feeding conditions.

According to Richard et al. (1991), all methods for condition analysis have their limits, some are too time-consuming while others require large samples or are valid only for particular larval stages. Last but not the least, the amount of money spent on this kind of methodology is extremely high and results are comparatively poor in accuracy. This study shows that time tables for the first feeding time can be obtained easily without using nucleic acid

derived indexes by IGR. In spite of the lack of correlation between IGR and RNA/DNA ratios in fed hatchlings, IGR still seems to be the most appropriate evaluator of cuttlefish growth and condition in controlled environments because it can be applied throughout the life cycle and is less expensive and time consuming. Forsythe (1993) stated that exponential growth patterns of some temperate cephalopods mean that very small changes in the growth rates of juveniles will translate into large differences in the adults. These small changes cannot be measured by nucleic acid derived indexes because of the variation associated with this method and described earlier. Nevertheless, it is possible that nucleic acid derived indexes could be used as tools to evaluate recruitment and wild larval condition and to evaluate condition of cuttlefish hatchlings in ecologic and fisheries research. Thus, the present work could be seen as a new approach to the determination of standard nutritional condition patterns to be used when studying wild cuttlefish hatchlings condition. However, much work still has to be done concerning these indexes at different temperatures and under controlled conditions, to obtain some data that can be used as control to be applied.

According to Jackson and Choat (1992), short lifespan species display exponential or linear growth. Because of this, these animals spend about half of their life as small juveniles. Moltchanivskyj and Martinez (1998) added that this may not be a disadvantage to their survivorship, and that condition of these juvenile marine organisms, rather than size, may play an important role in population dynamics. According to Van Heukelem (1979), slow growth by under-nutrition results in individuals maturing at smaller sizes, whereas, if growth rates are reduced by lower temperatures, then maturation will occur at larger sizes. Based on this assumption, Moltchanivskyj and Martinez (1998) stated that the effects of temperature and nutrition on growth differ. Taking all this into account, laboratory determination of nucleic acid derived indexes patterns could provide some answers and clues about cuttlefish condition in the wild, and the associated recruitment. Nevertheless, they cannot be used as precise tools to evaluate cuttlefish condition during the first stages of their life, because they are not accurate enough.

ABSTRACT The heritability of growth of juvenile *Strongylocentrotus nudus* was analyzed using quantitative genetic methods. Twenty-one half-sib groups and 60 to 63 full-sib groups of juveniles were obtained by artificial fertilization of three to five females by single males based on a nested design. The body weight (g) and test diameter (cm) of the young was measured 3 and 5 months after metamorphosis. Maternal component estimates are significantly greater than paternal component estimates for both weight and diameter at both ages. Greater maternal components suggest large non-additive genetic effects that could not be differentiated with the available data. Estimates of heritability in the narrow sense calculated from the additive genetic component using a paternal half-sib correlation analysis ranged from 0.2167–0.4565 for weight and 0.2059–0.4998 for diameter. The results indicate significant maternal effects. The strength of the nested design and the paternal half-sib correlation analysis used in this study make the estimate the most precise and unbiased reported to date.

KEY WORDS: sea urchin, *Strongylocentrotus nudus*, growth, heritability

INTRODUCTION

Sea urchins are one of the most important aquaculture species in the world. The gonads have long been used as a luxury food and as a food source by common people in many countries (Hobson & Chave 1990, Shimabukuro 1991, Hagen 1996). Because of over-fishing, interest in aquaculture of sea urchins has increased greatly (Hagen 1998, Lawrence et al. 2001). One of the most important species for aquaculture is *Strongylocentrotus nudus* (Hagen 1996, Agatsuma 1998). Current culture of *S. nudus* has used seeds obtained from wild individuals (Gao & Chang 1999, Liao & Qiu, 1999). Analysis of populations of *S. nudus* in Japanese waters shows considerable range in size of small individuals, presumably of single cohorts (Agatsuma 1997). This could result from interaction of genetic characteristics and the environment. Vadas et al. (2002) found evidence for intrinsic variability in field populations of *Strongylocentrotus droebachiensis*. It is important to document the degree of heritability of growth in sea urchins because of its implications for both fisheries and aquaculture.

Demonstration of heritability is best done with comparisons of half-sib groups because they are less likely to be affected by environmental influence (Gjedrem 1992). Sib analysis techniques have been used for several important aquaculture species (Mallet et al. 1986, Rawson & Hilbish 1990, Hadley et al. 1991, Crenshaw et al. 1991, Newkirk et al. 1977, Benzie et al. 1997). The purpose of this study is to estimate heritability of growth in terms of body weight and diameter of juvenile *Strongylocentrotus nudus*.

MATERIALS AND METHODS

Experimental Design

This study used a classic nested mating design developed by Comstock and Robinson (1952) to partition the phenotypic varia-

tion in juvenile growth into its genetic and non-genetic causes. In this experiment each of 21 male *Strongylocentrotus nudus* was mated to 3 to 5 females, therefore generating 63 full-sib families and 21 half-sib families. The effects of males and females nested within males on growth were separated using nested analysis of variance (ANOVA). Juveniles were weighed and their diameters measured at 3 and 5 months of age.

Genetic Analysis

The covariance among full- and half-sibs provides the basis for the separation of phenotypic variance into genetic and environmental components of variance. The covariance among full- and half-sibs are calculated from the observed components of variance obtained from a three-level nested, unbalanced ANOVA (Table 1) and the General Linear Models procedure of the statistical analysis system (SAS) (Freund et al. 1986).

The experiment was a three-level classic nested, unbalanced design. Therefore the number of offspring in dams and in sires and in dams within sires should revise ("revise" means adjust). The effective means were computed using the equations:

Effective mean number of offspring in dams within sires

$$K_1 = [N - \sum(n_{ij}^2/dn_i)]/(D - S)$$

Effective mean number of offspring in dams:

$$K_2 = [\sum(n_{ij}^2/dn_i) - \sum(n_{ij}^2/N)]/(S - 1)$$

Effective mean number of offspring in sires:

$$K_3 = (N - \sum dn_i^2/N)/(S - 1)$$

in which S = number of sires, D = number of dams, n_{ij} = number of offspring of the i-th sire and j-th dam, dn_i = number of offspring of i-th sire, N = sum of number of offspring of all sires or all dams.

The phenotypic variance (V_p) was separated into the additive genetic variance (V_A), non-additive genetic variance (V_N) and environmental variance (V_E), and the environmental variance (V_E) was separated into the common environmental variance (V_{EC}) and the specific environmental variance (V_{ES}) using the standard sepa-

This is contribution number G1999012009 of 973 from the Chinese National Fundamental research project and Chinese High Technology Plan (2002AA628170).

TABLE 1.
Analysis of variance for components of phenotypic variation.

Source of Variance	Degree of Freedom (df)	Sum of Squares (SS)	Mean Square (MS)	Expected Mean Square E (MS)
Dams	F × M - 1	SS _M		
Sires	F - 1	SS _F	MS _F	$\sigma^2 + k_2 \sigma_M^2 + k_3 \sigma_F^2$
Dams/sires	F × (M - 1)	SS _{M(F)}	MS _{M(F)}	$\sigma^2 + k_1 \sigma_M^2$
Offspring (error)	F × M × (n - 1)	SS	MS	σ^2
Total	N - 1	SS _T		

ration of variance components (Falconer 1989). The causal components of variance were estimated from the full- and half-sib covariance using the relationships in Table 2.

Heritabilities were computed using the relationships:

$$h^2 = V_A / [V_A + V_{NA} + V_E]$$

Thus heritabilities in the narrow sense of paternal half-sib and maternal half-sib and full-sib were computed using the respective relationships:

$$\begin{aligned} h_{HS(S)}^2 &= 4 \times \sigma_S^2 / (\sigma_S^2 + \sigma_D^2 + \sigma^2) \\ h_{HS(D)}^2 &= 4 \times \sigma_D^2 / (\sigma_S^2 + \sigma_D^2 + \sigma^2) \\ h_{FS(D,S)}^2 &= 2 \times (\sigma_S^2 + \sigma_D^2) / (\sigma_S^2 + \sigma_D^2 + \sigma^2) \end{aligned}$$

Test of significant of heritability:

$$t = h^2 / \sigma_{h^2}$$

Paternal half-sib:

$$\begin{aligned} V_{(h^2)} &= \left(\frac{4}{\sigma_P^2} \right)^2 \left[V \left(\frac{MS_S}{k_3} \right) + V \left(\frac{MS_D}{k_3} \right) \right] \\ \sigma_{h^2} &= \frac{4}{\sigma_P^2} \sqrt{\frac{2}{k_3^2} \left[\frac{MS_S^2}{S-1} + \frac{MS_D^2}{N-D} \right]} \end{aligned}$$

Maternal half-sib:

$$\begin{aligned} V_{(h^2)} &= \left(\frac{4}{\sigma_P^2} \right)^2 \left[V \left(\frac{MS_D}{k_1} \right) + V \left(\frac{MS_E}{k_1} \right) \right] \\ \sigma_{h^2} &= \frac{4}{\sigma_P^2} \sqrt{\frac{2}{k_1^2} \left[\frac{MS_D^2}{D-S} + \frac{MS_E^2}{N-D} \right]} \end{aligned}$$

Full-sib:

$$\sigma_{h^2} = 2 \sqrt{\frac{2(1-r_{FS})^2[1+(k_1-1)r_{FS}]^2}{k_1(k_1-1)(D-1)}}$$

Experimental Animal

Collection and Maintenance

Parental *Strongylocentrotus nudus* were taken from a cultured population in Dalian Bay on the northern coast of the Yellow Sea on 10 September 2001. These individuals were held at 18–22°C under 500 × 1 illumination and fed *Laminaria japonica* ad libitum for 32 days before spawning on 12 October 2001.

Fertilization

Individuals were removed from the aquaria and allowed to drain for 30 minutes before 1 mL 0.5 M KCL was injected into the coelomic cavity via the peristomial membrane. They were placed on the tops of flasks filled with sea water and the eggs and sperm collected from each individual for 30–60 minutes.

The eggs of each female were fertilized with sperm from a single male. Approximately 150,000 eggs from each female were placed in 100-L containers. Sperm were diluted 1000-fold (Uehara et al. 1990) and a small amount of the diluted sperm was added to the eggs. Fertilization success was examined microscopically. The fertilized eggs were washed two to three times to remove excess sperm. The embryos were layered on the bottom of flasks and transferred into a 50-L container to develop at 17–21°C at a density of four to five individuals/mL. Normal plutei developed in 30–35 h. (Rahman et al. 2000, Rahman et al. 2001).

Rearing

The larvae were transferred to 100-L containers of filtered sea-water at 16°C. Densities of larvae from the 2-arm to the 8-arm stage were maintained at one to two individuals/mL. The water was changed twice daily. The larvae were fed *Chaetoceros gracilis*. Light was maintained at <300 LX. A small amount of air was bubbled into the water. After 3 months the juveniles from each fertilization group were placed separately into plastic cages suspended in a large pool. The juveniles were fed fresh *Laminaria*

TABLE 2.
Relationships between the covariance of full and half-sibs and causal components of phenotypic variance.

Component of Variance	Covariance Components	Causal Components	Calculation of Component of Variance
σ_F^2	COV _{HS}	1/4 V _A	{MS _F [(MS _{M(F)} - MS _E)/k ₁] × k ₂ - MS _E }/k ₃

Analysis of Variance of Body Weight and Test Diameter of Offspring

Analysis of variance demonstrated great differences in body weight and diameter of juveniles from different females mated with the same male and between males at both 3 and 5 months of age (Table 4).

Effective mean number of offspring for sires and dams after 3 months was computed as follows: effective mean number of offspring in dams within sire is $K_1 = 34.689$, in dams is $K_2 = 38.821$, and in sires is $K_3 = 107.719$. Effective mean number of offspring for sires and dams after 5 months was computed as follows: $K_1 = 33.505$; $K_2 = 36.831$; $K_3 = 109.268$.

The causal components of variance were estimated from the full- and half-sib covariance using the relationships in Table 5.

Estimations of Heritability of Body Weight and Test Diameter of Offspring

Heritabilities in the narrow sense of paternal half-sib and maternal half-sib and full-sib of body weight and diameter of 3-month-old *Strongylocentrotus nudus* were calculated on the result of component of variance and test ($t = h^2/\sigma_h^2$) of significant of heritability respectively as Table 6.

All of the heritability in the narrow sense of sire half-sib and the heritability in the broad sense of dam full-sib of body weight, test diameter of *S. intermedius* were significantly different from zero (t -test, $P < 0.01$).

Estimated heritability was somewhat different among the sire heritability, dam heritability, and the pooled (combined) heritability for all three traits. The estimates of dam heritability were higher than that of sire heritability, and the pooled (combined) heritability was moderate.

DISCUSSION

Predicted heritabilities of larval growth have been reported for full-sib correlation analysis for *Crassostrea virginica* (Lannan 1972, Haley et al. 1975, Newkirk et al. 1977) and *Penaeus vannamei* (Carr et al. 1997) and half-sib correlation analysis for *Mercenaria mercenaria* (Rawson & Hilbish 1990), *Macrobrachium rosenbergii* (Malecha et al. 1984), *Penaeus vannamei* (Carr et al. 1997, Benzie et al. 1996), and *Penaeus stylirostri* (Benzie et al. 1996). Predicted heritabilities of shell traits in wild littorina saxatilis populations have been reported for full-sib correlation analysis and offspring-mother regression (Carballo et al. 2001). Estimates of heritabilities in the narrow sense generally ranged from 0.2–0.7. Realized heritability for increase in rate of growth in northern quahog and *Argopecten irradians concentricus* (Crenshaw et al. 1996, Crenshaw et al. 1991) and realized heritability estimates for growth in the Chilean oyster *Ostrea chilensis* (Toro et al. 1995). In our study, the estimates of heritabilities in the narrow sense for

body weight at 3–5 months of age ranged from 0.217–0.457, consistent with those reported for other species. However, estimates are based on full-sib families bias heritabilities upwards when dominance and maternal effects are present (Lester, 1988). Because of the nested design and a paternal half-sib correlation analysis used, the estimate reported here is more precise and unbiased. This is the first report of heritability in the narrow sense reported for sea urchins.

An animal model includes a random effect for the additive genetic effect of each individual; and incorporates a complete set of additive genetic relationships among all individuals; and allows an unbiased estimation of variance components, even for the data involving selection and non-random mating (Gall & Bakar 2002, Sorensen & Kennedy 1986, Su et al. 1997). In this investigation full-sib family was taken as a random effect in a simple random model to account for the covariance among full-sibs caused by common environmental, dam and non-additive genetic effects, and half-sib family was used to account for covariance among half-sibs caused by common environmental, dam, sire, and non-additive genetic effects. The results from the analyses based on this model were expected to be unbiased estimates of genetic parameters for the base population.

The much larger heritabilities computed from the female additive genetic component indicate the female genetic component still contain common environmental effects, maternal effects or non-additive genetic variance in the body weight or diameter. Dam effects are omnipresent in the study. The fact that the juvenile phase may indicate that the quality of yolk reserves plays a role in early development. Dam effects may persist after the onset of exogenous feeding. Crandell and Gall (1993) reported that dam effects persist up to 2 years in rainbow trout and up to 18-month-old Arctic char (Nilsson 1994).

The estimated heritability indicates significant additive genetic variation for body weight and test size all over the sampling periods. Sire heritability for the different variables were lower than dam heritability in many cases. However, all heritabilities in the narrow sense of body weight, test diameter of *S. intermedius* were significantly different from zero ($P < 0.01$). The heritabilities in the narrow sense estimate obtained from this experiment indicate there is sufficient variation in the base population of sea urchins to respond to natural or artificial selection on juvenile growth weight. This justifies selection of juveniles based on growth characteristics for cultured brood stock.

A SET OF TESTS FOR THE PHENOTYPIC IDENTIFICATION OF CULTURABLE BACTERIA ASSOCIATED WITH GALICIAN BIVALVE MOLLUSC PRODUCTION

J. A. GUISANDE, M. MONTES, R. FARTO, S. P. ARMADA, M. J. PÉREZ AND T. P. NIETO*

Área de Microbiología, Departamento de Biología Funcional y Ciencias de la Salud, Facultad de Ciencias, Universidad de Vigo, Vigo, Spain

ABSTRACT To select a set of biochemical tests that provide a rapid identification of culturable bacteria associated with Galician bivalve molluscs cultures, the phenotypic diversity of some bacterial species was investigated. A total of 488 strains isolated from water, phytoplankton, larva, seed and reproductive phases in oysters and clams cultures in Galicia (NW of Spain) and 51 type and reference strains were characterized by 92 physiologic, morphologic and biochemical tests. The 80% of isolates were facultative anaerobes and the remaining 20% were aerobes. Using numerical taxonomy and probabilistic methods, 57% of facultative anaerobic isolates could be identified: *Vibrio aestuarii*, *V. splendidus* biotype 1, *V. alginolyticus*, *V. mytili*, *V. (Listonella) anguillarum*, *V. salmonicida*, *V. furnissii* and *V. orientalis*. The predominant aerobic strains were *Shewanella* spp., *Pseudoalteromonas* spp., *Pseudomonas* spp. and *Alcaligenes denitrificans*. *Vibrio* was the most frequently isolated genus from oysters, clams and their culture water. *Pseudomonas* and *Pseudoalteromonas* were the main isolated genus from phytoplankton samples. A selection of a set of tests for the phenotypic and presumptive identification of the main culturable bacterial groups was possible. Since this set of tests provides a rapid identification, it will be very useful in the quality control of bivalve mollusks, in industrial treatment plants or in the work of hygiene and health control staff.

KEY WORDS: oysters, clams, presumptive bacterial identification, aerobic bacteria, facultative anaerobic bacteria, *Vibrio*, numerical taxonomy

INTRODUCTION

The culture of bivalve molluscs represents the 8% of the world fish production and the 26% of the world aquaculture production. Bivalve mollusk production has been increasing in the last 50 years worldwide, with a triplication of its production in the last decade (Lovatelli 2003). Spain is the main bivalve mollusks producer in Europe, with an annual production of 275,000 tons, where the main culture volume is concentrated in Galicia (NW of Spain).

The development of modern techniques allows the maintenance of cultures with a high density of mollusks, making intensive cultures possible but also increasing the risks and consequences of infectious outbreaks.

The association of microorganisms with animal tissues can be symbiotic or pathogenic or, as in the case of mollusks, coincidental with the process of filter feeding. The great phenotypic diversity of these bacterial strains makes identification of isolates difficult. Also, certain bacterial species have been described as pathogenic to bivalve mollusks and/or to people who consume them. These species include: *V. tapetis* (Paillard et al. 1989, Castro et al. 1993, Castro 1994, Robledo et al. 1994, Borrego et al. 1996), *V. tubiashii* (Tubiash et al. 1965), *V. vulnificus* (Tracket et al. 1984, Horré & Günter 1996), *V. (Listonella) anguillarum* (Grischowsky & Liston 1974, Elston 1989, Montilla et al. 1994), *V. fluvialis* (Lee et al. 1981), *V. pelagius* (Montilla et al. 1994), *V. mimicus* (Mattè et al. 1994), *Vibrio cholerae* (Kaper et al. 1983), *V. parahaemolyticus* (Kaper et al. 1983), *V. alginolyticus* (Grischowsky & Liston 1974, Elston 1989), or *Plesiomonas shigelloides* (Prescott et al. 1999).

The aim of this study is to identify the bacteria associated with the culture of bivalve molluscs in Galicia to select tests that can be useful to separate environmental bacteria species associated with mollusks cultures and the most frequent potentially pathogenic strains. Such a set of tests will be very useful for undertaking the

quality control of bivalve mollusks, in industrial treatment plants or in the work of hygiene and health control staff.

MATERIALS AND METHODS

Bacterial Strains

Samples were obtained from different stages (seed, larval, and reproductive) in cultures of clams (*Ruditapes decussatus*, *Venerupis pullastra*, *Tapes japonica*) and oysters (*Ostrea edulis*), as well as from the surrounding water and phytoplankton. All animals were washed first to remove loosely associated bacteria and contaminants. All sterilizations were done at 121°C for 15 min and all filtrations through 0.22-µm pore size porosity filters. Reproductive bivalve mollusks (50 g of meat and intervalval liquid) were homogenized in 100 mL of sterile marine phosphate-buffered saline (PBS) (20 g of NaCl per liter, 0.2 g of KCl per liter, 1.15 g of PO₄HNa₂ per liter, 0.2 g of PO₄H₂K per liter; pH 7.1 to 7.2). Bivalve mollusks in the larval and seed stages (50 units each) were separately homogenized in 100 mL of PBS. Phytoplankton samples were obtained through the filtration of 1000 mL of water and their suspension in 100 mL of PBS. Serial dilutions (1:10; 1:100; 1:1000) of all these samples were plated in duplicate on Marine Agar (MA, Cultimed, Barcelona, Spain) and Thiosulphate-Citrate-Bile-Sucrose (TCBS, Cultimed), including water samples. Plates were incubated at 22°C for 4 days. Five colonies of each morphology were picked off and streaked on MA to obtain pure cultures, which were inoculated on Nutritive Broth (Cultimed) with 2% (w/v) NaCl (Panreac, Barcelona, Spain) and 15% (v/v) of glycerol (Panreac) for their conservation at -80°C.

Sampling was carried out over 12 consecutive months (1 sample a month) in bivalve mollusks culture systems located on the Galician coasts at: Bueu, O Grove, Ribadeo, Couso, Malpica, and Vilagarcía de Arousa. According to these methods, 480 strains were isolated.

The following 51 type and reference strains were included in this study for comparative purposes and were characterized under the same conditions and using the same tests as for the remainder

Phenotypic Characterization

Bacterial strains were characterized by 92 physiologic, morphologic, and biochemical tests. Cultures grown during 24 h at 22°C on Tryptic Soy Agar (TSA, Cultimed) and supplemented up to 2% (w/v) NaCl (TSA 2%) were used as inocula. Unless otherwise indicated, all incubations were undertaken at 22°C, commercial media were supplemented up to 2% (w/v) NaCl and results were read after 48 hours.

All tests and methods were carried out as described by Montes et al. (1999), except that the hydrolysis of urea was tested on Stuart's Urea Broth (Pronadisa, Madrid, Spain) and the Gram character was performed using the KOH 3% (v/v) (Analema, Vigo, Spain) method (Buck 1982).

All tests were assayed on plates and were spot inoculated with a multipoint inoculator, except for O/F (oxidative or fermentative metabolism of glucose), ODC (ornithine decarboxylase), LDC (lysine decarboxylase), HDC (histidine decarboxylase), ADH (arginine dihydrolase), Voges-Proskauer, methyl red, Kligler, nitrate reduction, indole production, and the hydrolysis of urea when tests were performed in tubes.

Coding of Data

Results were coded using the following criteria: 1 for positive results, 0 for negative results and 9 for non-comparable or missing values. Data were processed with the NTSYS-pc, version 1.8 (Rohlf 1994). Similarity matrices were calculated using the Simple Matching coefficient (S_{SM}) and Jaccard's coefficient (S_J). Phenotypes

were clustered using the Unweighted Pair Group Method, with Arithmetic mean (UPGMA). The correlation between the dendrogram and each similarity matrix (cophenetic correlation) was determined using the cophenetic correlation coefficient (r).

The reproducibility of the tests was evaluated by analyzing 10% of strains in duplicate, as suggested by Sneath and Johnson (1972).

For phenotypes that could not be identified by numerical taxonomy methods, probabilistic identification was performed with the "Probabilistic identification of bacteria" program, version 1.10 (Bryant 1995). This computer program includes the data matrices of Bryant et al. (1986) and Alsina and Blanch (1994a), providing the most suitable probabilistic identification of each phenotype.

RESULTS

Numerical Taxonomy

Seventy-six per cent of a total of 488 strains were isolated in MA and the remaining 24% in TCBS. Some 80% of isolates were Gram negative, oxidase positive and with the ability to ferment glucose (facultative anaerobic strains). The remaining 20% were Gram negative, oxidase positive, and non-fermentative strains (aerobic strains).

The probability of an erroneous result was $P = 2.596\%$ for aerobic strains and $P = 2.045\%$ for facultative anaerobic strains. According to the criteria suggested by Sneath and Johnson (1972), each of these values and their average (2.3078%) are acceptable values (lower than 5%) and are indicative of good reproducibility.

Five tests were deleted from the data matrices because of their variances (higher than 0.1, according to Bryant et al. 1986): acid production from arbutine, use of aspartate or alginate as sole carbon source, production of lipase using tween 20 as substrate and β -hemolysis.

Furthermore, 9 tests giving the same result were also eliminated for aerobic strains: growth at 22°C (+: positive result), growth at pH 7.5 (+), oxidase (+), histidine decarboxylation (-: negative result), glucose fermentation (-), Voges-Proskauer test (-), acid production from inositol (-) or L-rhamnose (-), and the Gram character, that was negative. For facultative anaerobic strains, 9 tests were deleted from the data matrix, as they had always shown the same result: growth at 22°C (+), growth at pH 4.5 (-), oxidase (+), glucose fermentation (+), glucose on Kligler (+), acid production from inositol (-) or raffinose (-), motility (+) and the Gram character, that was negative.

For the aerobic strains, the number of final matrices was 106 (strains) \times 78 (tests) and for facultative anaerobic strains the number was 434 (strains) \times 78 (tests).

Similarities were calculated using the S_{SM} and S_J coefficients. Phenotypes were clustered using the UPGMA. Cophenetic correlation showed the best fit (Rohlf 1994) using the S_J coefficient ($r = 0.81621$ for aerobic strains and $r = 0.80555$ for facultative anaerobic strains).

This study focuses on clustered isolates: 57% of aerobic strains (with a S_J /UPGMA similarity level of 69%) and 88% of facultative anaerobic strains (with a S_J /UPGMA similarity level of 69%).

Aerobic Strains

A phenotypic dendrogram constructed using the S_J /UPGMA analysis included 23 phenotypes (Fig. 1) with a similarity level of 69%, clustering 57% of aerobic isolates. Only 4 isolates were identified:

*: A reference strain was included within as identified group

Figure 1. Simplified dendrogram of aerobic strains showing the phena defined with a value of $S_j \geq 69\%$.

Shewanella hanedai (one isolate), *Alcaligenes denitrificans* (one isolate), *Pseudoalteromonas espejiana* (one isolate) and *Pseudomonas nautica* (one isolate).

Independently of the S_j similarity level and due to the great diversity of unidentified aerobic isolates that was found, five different main groups were defined (see Fig. 1) taking shared characteristics of close phena into account: *Shewanella* spp. (16% of clustered isolates), low-NaCl requirements for growth (16% of isolates), *Pseudoalteromonas* spp. (15% of isolates), *Pseudomonas* spp. (8% of isolates), and *Alcaligenes denitrificans* (1% of isolates).

In addition to the tests for which the same result was obtained, as described earlier for all aerobic strains, clustered aerobic isolates always displayed the same response for the following tests: growth at 28°C (+), pH 4.5 (-), pH 9 (+), growth in 3.5% (w/v) NaCl (+), H_2S production on TCBS (-), catalase reaction (+), ODC and LDC (-); oxidative character on O/F medium (+), utilization of glucose or lactose on Kligler medium (-), methyl red reaction (-), indole production (-), α -haemolysis (-), acid production from amygdaline, L-arabinose, D-cellobiose, ethanol, D-fructose, D-galactose, glycerol, lactose, D-mannitol, D-melibiose, D-raffinose, ribose, sucrose, salicin, sorbitol or D-trehalose (-); degradation of urea, chitin, gelatin, casein, DNA, lecithin, chondroitin, cellulose

or agar (-); utilization of citrate as sole carbon source (-), and motility (+).

Differential phenotypic characteristics are given in Table 1. The main characteristics that allow different groups to be defined are cited below:

Shewanella spp.

This group was constituted by phenon 1 (two isolates), phenon 2 (two isolates), phenon 3 (four isolates), phenon 4 (three isolates), phenon 5 (one isolate and the reference strain of *Shewanella hanedai*), and phenon 6 (three isolates). All showed a mesophilic character (growth between 10°C and 28°C) and had NaCl requirements for growing, despite being unable to tolerate high NaCl concentrations (7% or even 5% in some cases). Half of them were able to produce H_2S on Kligler medium, and most grew on TCBS medium and carry out nitrate reduction, as well as growth maintenance at pH 10 and sensitivity to tetracycline (30 µg/disc). They were generally unable to use any of the assayed substrates as sole carbon source.

Low-NaCl Requirements for Growth

This group included phenon 8 (7 isolates), 10 (4 isolates), 12 (2 isolates), and 13 (2 isolates). The main characteristics of this group are growth maintenance in low NaCl concentrations (0.5%), which indicates the low NaCl requirements for growth, as well as NaCl tolerance of up to 7%, growth maintenance at pH 10 and the use of different substrates as sole carbon source: acetate, β -alanine, DL-alanine, L-arginine, L-lysine, malonate, L-proline, propanol, pyruvate, L-serine or succinate. All had sensitivity to tetracycline (30 µg/disc).

Pseudoalteromonas spp.

This group included the following phena: 7 (1 isolate and the reference strain of *Pseudoalteromonas espejiana*), 16 (2 isolates), 17 (3 isolates), 18 (3 isolates), 19 (3 isolates), and 20 (2 isolates). A reference strain of *Pseudoalteromonas haloplanktis* was clustered close to phenon 20. All these strains showed NaCl requirements for growth, tolerating most of them NaCl concentrations of up to 7%. These strains were able to grow at 28°C (but not usually at 37°C) and to carry out starch degradation. Glycine and L-proline were the sole substrates they could use as carbon sources.

Pseudomonas spp.

This group was constituted by phenon 15 (one isolate was clustered with reference strains of *Pseudomonas putida* and *Pseudomonas fluorescens*), phenon 21 (2 isolates), phenon 22 (2 isolates) were clustered with a reference strain of *Pseudomonas nautica*, and phenon 23 (2 isolates). Most of them were able to grow between 10°C and 28°C (even at 44°C in some cases), at pH 10 and had low-NaCl requirements for growth (0.5% NaCl). They were able to use acetate, L-proline and pyruvate as sole carbon sources and were sensitive to tetracycline (30 µg/disc).

Alcaligenes denitrificans

One bacterial isolate was clustered with the reference strain of *Alcaligenes denitrificans* (phenon 9). Both were able to grow between 10°C and 37°C and at pH 10; showed low-NaCl requirements for growth and were not able to tolerate high NaCl concentrations (7% or even 5% in some cases). They were able to carry out nitrate reduction and the use of different substrates as sole carbon source, such as acetate, β -alanine, DL-alanine, glycine,

Group 1.-*Shewanella* spp.; Group 2.-Low-NaCl requirements for growth; Group 3.-*Pseudoalteromonas* spp.; Group 4.-*Pseudomonas* spp.; Group 5.-*Alcaligenes denitrificans*.

Discriminatory tests for the biochemical identification of strains isolated from bivalve molluscs that are Gram negative, motile, oxidase positive, aerobic and able to grow at 22°C strains are expressed in bold.

Criteria (data are expressed in percentage of positive results): ND: No data; +: Positive result ($\geq 90\%$ of positive results); -: Negative result ($\leq 10\%$ of positive results); (+): Mainly positive results ($\geq 70\% < 90\%$ of positive results); (-): Mainly negative results ($\geq 10\% < 30\%$ of positive results); v: Variable results ($> 30\% < 70\%$ of positive results).

L-lysine, malonate, L-phenylalanine, L-proline, propanol, pyruvate, or L-serine. They were sensitive to tetracycline (30 µg/disc), but not to O/129 (150 µg/disc).

The following 6 tests (Table 1) are proposed as discriminatory and useful for the biochemical identification of Gram negative, motile, oxidase positive, aerobic, and able to grow at 22°C strains associated with the culture of Galician bivalve molluscs: growth in

different concentrations of NaCl (0.5% and 7%), nitrate reduction, growth on TCBS medium and the use of DL-alanine or malonate as sole carbon source.

Facultative Anaerobic Strains

A dendrogram was obtained applying Jaccard's similarity coefficient and using the UPGMA as a clustering method. In total, 41

phena (clustering 88% of facultative anaerobic strains) were established with a S_J /UPGMA similarity level of 69% (Fig. 2). The inclusion of reference strains allowed the identification of eight phena: *Vibrio aestuarianus* (22% of isolates), *V. alginolyticus* (8% of isolates), *V. (Listonella) anguillarum* (7% of isolates), *V. salmonicida* (3% of isolates), *V. furnissii* (1% of isolates), *V. orientalis* (1% of isolates), and *Photobacterium damsela* subsp. *piscicida* (1% of isolates). Five phena were identified as *V. splendidus* biotype I (8% of isolates), *V. mytili* (7% of isolates) and *Photobacterium phosphoreum*/*Plesiomonas shigelloides* (2% of isolates), showing a probability of identification of over 75%, according to the data matrices of Bryant et al. (1986) and Alsina and Blanch (1994a) ("Probabilistic identification of bacteria" program, version 1.10, Bryant, 1995). Some 59% of all Gram negative, facultative anaerobic, motile and oxidase positive isolates could be

identified by these methods. The use of updated keys for biochemical identification of *Vibrio* species (Alsina & Blanch 1994b) did not provide an improved identification. The remaining 28 unidentified phena were assigned as "*Vibrio* spp."

In addition to the tests for which the same result was obtained, as described earlier for all facultative anaerobic strains, clustered facultative anaerobic isolates always displayed the same response for the following tests: growth at pH 7.5 (+), pH 9 (+), pH 10 (+), H_2S production on TCBS (-), HDC (-), utilization of lactose in Kligler medium (-), H_2S production in Kligler medium (-), Voges-Proskauer reaction (-), methyl red reaction (+), acid production from amygdaline, L-arabinose, ethanol, lactose, D-melibiose, L-rhamnose, salicin or sorbitol (-), degradation of urea or cellulose (-), and sensitivity to tetracycline (30 μ g/disc) (+).

For each identified group (Table 2), in keeping with previous description by other authors and in addition to the responses already mentioned for all facultative anaerobic strains, the main characteristics were:

*: A reference strain was included within an identified group

Figure 2. Simplified dendrogram of facultative anaerobic strains showing the phena defined with a value of $S_J \geq 69\%$.

V. aestuarianus

This group was constituted by phenon 5 (94 isolates and a reference strain of *V. aestuarianus*). Strains included in this phenon showed a negative result for the following tests: lysine and ornithine decarboxylation, growth at 37°C and in 10% NaCl. However, they showed a positive result for Thornley's arginine dihydrolase test, growth at 28°C, nitrate reduction, starch degradation, acid production from D-mannitol, use of citrate as sole carbon source, and susceptibility to O/129 (150 μ g/disc).

V. splendidus biotype I

This group included phenon 1 (22 isolates) and phenon 17 (12 isolates). These bacterial strains were unable to grow at 37°C, in 10% NaCl or in crystal violet. They were unable to use β -alanine, inulin, L-lysine, malonate, L-phenylalanine, propanol, or L-tryptophan as sole carbon source. They showed negative responses for ornithine or lysine decarboxylase tests, and positive results for acid production from D-cellobiose, D-mannitol and ribose, use of L-proline as sole carbon source, and growth at 28°C.

V. alginolyticus

This group was formed by phenon 21 (33 isolates and a reference strain of *V. alginolyticus*). Isolates included in this phenon showed a negative result for Thornley's arginine dihydrolase test and use of propanol as sole carbon source. However, they were able to carry out nitrate reduction, hydrolysis of casein, indole production, growth on 10% NaCl and at 44°C, lysine decarboxylation, acid production from sucrose or D-trehalose, use of acetate, β -alanine, DL-alanine, L-arginine or citrate as sole carbon source. They showed positive results for catalase test and a variable result for ornithine decarboxylation.

V. mytili

This group was constituted by phenon 7 (10 isolates) and phenon 14 (22 isolates). These strains showed negative responses in tests for growth at 37°C, lysine or ornithine decarboxylation, hydrolysis of DNA or gelatin and acid production from D-mannose. They showed a positive result for Thornley's arginine dihydrolase test and acid production from sucrose.

"N" indicates the number of isolates included in each phenon: 1.-*Vibrio splendidus* biotype I; 4.-*V. (Listonella) anguillarum*; 5.-*V. aestuarianus*; 6.-*V. anguillarum*; 7.-*V. mytili*; 14.-*V. mytili*; 17.-*V. splendidus* biotype I; 18.-*V. salmonicida*; 21.-*V. alginolyticus*; 22.-*V. furnissii*; 24.-*Photobacterium damsela* subsp. *piscicida*; 29.-*V. orientalis*.

Discriminatory tests for the biochemical identification of strains isolated from bivalve molluscs that are Gram negative, motile, oxidase positive, methyl red positive, facultative anaerobic and able to grow at 22 °C are expressed in bold.

Criteria (data are expressed in percentage of positive results): ND, No data; +, Positive result ($\geq 90\%$ of positive results); —, Negative result ($\leq 10\%$ of positive results); (+), Mainly positive results ($\geq 70\%$ < 90% of positive results); (—), Mainly negative results ($\geq 10\%$ < 30% of positive results); v, Variable results (>30% < 70% of positive results).

V. (Listonella) anguillarum

This group included phenon 4 (12 isolates and the reference strain of *V. (Listonella) anguillarum* NCIMB 571) and phenon 6 (17 isolates and the reference strain of *V. (Listonella) anguillarum* 43-F). These strains showed negative responses in tests for ornithine and lysine decarboxylase, growth in media containing crystal violet or 10% NaCl, growth at 37 °C and use of β -alanine, malonate, or propanol as sole carbon sources. They showed positive results in tests for catalase, nitrate reduction, indole production, Thornley's arginine dihydrolase, hydrolysis of starch or casein, and the use of L-proline as sole carbon source.

V. salmonicida

Phenon 18 (13 isolates and a reference strain of *V. salmonicida*). These strains were unable to carry out lysine or ornithine decarboxylation, growth in 10% NaCl or at 37 °C and hydrolysis of esculin or gelatin. They were able to grow at 4 °C and sensitive to O/129 (150 µg/disc).

V. furnissii

Phenon 22 (2 isolates and a reference strain of *V. furnissii*). These isolates had negative responses for the following tests: growth at 4 °C, in 10% NaCl or in crystal violet, ornithine or lysine decarboxylation, hydrolysis of chondroitin, acid production from D-cellobiose, and the use of malonate as sole carbon source. They showed positive results for Thornley's arginine dihydrolase test, nitrate reduction, catalase test, hydrolysis of starch or casein, acid production from D-mannitol or D-trehalose and use of L-arginine, L-proline, L-serine, or succinate as sole carbon source.

V. orientalis

Phenon 29 (2 isolates and a reference strain of *V. orientalis*). These strains showed negative results for growth at 37 °C and ornithine decarboxylation tests. However, they were able to grow at 28 °C; in 3.5% or 5% NaCl; showed positive results on indole production and nitrate reduction tests; were able to produce acid from D-fructose and sucrose; were sensitive to O/129 (150 µg/disc); and could use pyruvate as sole carbon source.

Ph. Damsela subsp. *Piscicida*

Phenon 24 (1 isolate and a reference strain of *Ph. damsela* subsp. *piscicida*). Both strains were unable to grow at 4 °C, on TCBS medium, carry out ornithine or lysine decarboxylation, indole production, hydrolysis of gelatin, acid production from D-cellobiose, glycerol, D-mannose, sucrose, or D-trehalose. Both strains showed positive results for the following tests: growth in 3.5% NaCl, catalase, and O/129 (150 µg/disc) susceptibility.

The following 12 tests (Table 2) are proposed as discriminatory and useful for the biochemical identification of Gram negative, motile, oxidase positive, methyl red positive, facultative anaerobic, and able to grow at 22 °C strains associated with the culture of Galician bivalve mollusks: Thornley's arginine dihydrolase, lysine decarboxylase (Moeller medium), indole production, growth in different NaCl concentrations (0.5% and 7% NaCl), nitrate reduction, growth at 4 °C, acid production from D-fructose, sucrose and D-trehalose, and the use of citrate and pyruvate as sole carbon source.

Bacterial distribution

Vibrio species were the predominant bacterial strains associated with the culture of bivalve mollusks (Table 3). Bacterial strains isolated from the seed stage in clams were identified as *V. aestuarianus* (facultative anaerobic isolates) or *Pseudoalteromonas* spp. (aerobic isolates). This may be due to the low number of bacterial strains isolated at this stage. The only aerobic strains isolated from the larval and reproductive stages in clams were identified as belonging to the genus *Shewanella*. The seed and reproductive stages of *Ostrea edulis*, the latter with the highest number of isolates, showed *Vibrio*, *Shewanella*, and *Pseudoalteromonas* species. A large variety of aerobic strains and different *Vibrio* species could be identified in the larval stage of *Ostrea edulis*. Species of *Vibrio*, *Photobacterium*, *Pseudoalteromonas*, and *Pseudomonas* were identified from water samples. The presence of the 2 main identified species (*V. aestuarianus* and *V. splendidus* biotype I) in water samples and associated with different phases in the culture of oysters demonstrates the influence of the microflora in the surrounding water. Aerobic strains with low-NaCl requirements for growth and able to tolerate concentrations of up to 7% (w/v) NaCl were isolated from clams, oysters, water,

and phytoplankton samples, revealing the influence of living in estuarine water.

Excluding samples isolated from phytoplankton, where facultative anaerobic strains were not detected, each remaining sample showed bacterial strains up to now unidentified.

DISCUSSION

A comparison between aerobic and facultative anaerobic strains reveals the existence of a wide diversity among the aerobic isolates. Although 352 facultative anaerobic isolates were clustered in 41 phena (see Fig. 2), and one already contained 94 of these isolates, only half of the aerobic strains could be clustered: 52 isolates in 23 phena (see Fig. 1). This shows a proportion of 8.59 facultative anaerobic strains per phenon, versus a ratio of 2.26 aerobic strains per phenon. For facultative anaerobic strains the isolates were very similar, unlike the aerobic isolates (Ortigosa et al. 1994b, Pujalte et al. 1999, Macián et al. 2000).

Shewanella, *Pseudoalteromonas* and *Pseudomonas* were the main aerobic bacteria groups and *Vibrio aestuarianus*, *V. splendidus* biotype 1, *V. alginolyticus*, *V. mytili*, and *V. (Listonella) anguillarum* were the predominant facultative anaerobic bacteria identified in this study as being associated with the culture of bivalve mollusks in Galicia. Other authors have identified these microorganisms from oysters, clams, and other bivalve mollusks with a different predominance of species: Ortigosa et al. (1994b) studied aerobic, gram negative bacteria associated with oysters and surrounding water in Valencia (Spain), identifying species of *Alteromonas*, *Shewanella*, *Deleya*, *Flavobacterium*, *Oceanospirillum*, *Pseudomonas*, and marine *Agrobacterium*-like organisms. Montilla et al. (1994) found that the most frequent *Vibrio* species associated with clams, oysters, and mussels in nurseries at the Ebro Delta (Spain) was *V. fluvialis* followed by *V. pelagius*, *V. tubiashii*, *V. splendidus*, *V. alginolyticus* and *V. parahaemolyticus*. Hariharan

et al. (1995) studied bacteria associated with oysters and mussels from six river systems in Prince Edward Island (Canada); they identified *V. (Listonella) anguillarum* as the most common species from oysters and *V. alginolyticus*, and *V. splendidus* as the most common from mussels, with the second largest group of bacteria being *Pseudomonas/Shewanella*. Pujalte et al. (1999) studied bacteria associated with the Spanish Mediterranean coast and found that *V. splendidus* and *V. harveyi* were the main bacteria associated with oysters, whilst *Halomonas*, *Alteromonas* and *Pseudomonas* were the principal groups identified from seawater. Mauger et al. (2000) studied brackish waters and mussels in the northeast of Sicily (Italy) and identified the following *Vibrio* species: *V. fluvialis*, *V. alginolyticus*, *V. parahaemolyticus*, *V. vulnificus*, and *V. mimicus*. Castro et al. (2002) found that the main *Vibrio* species associated with cultured Manila clams from the Atlantic coast of south-western Spain were *V. tubiashii*, *V. splendidus* biotype 1, and *V. harveyi*. Our results are in agreement with all the above mentioned studies, which show a clear prevalence of different species of genus *Vibrio*, followed by a different dominance of aerobic strains. This demonstrates the considerable influence of the specific natural conditions of each region on the colonization of cultures of bivalve mollusks.

The characteristics described in this study for each identified group are consistent with results previously reported by other authors for facultative anaerobic (West et al. 1986, Pujalte et al. 1993, Alsina & Blanch 1994a, Cerdá-Cuéllar et al. 1997, Thyssen et al. 1998) and aerobic strains (Bowman 1998, Sawabe et al. 1998, Venkateswaran et al. 1999), whom groups establishment allowed a great identification but only up to a genus level. As shown in Tables 1 and 2, the results of this study make it possible to improve the characterization of *Vibrio* species and aerobic isolates. The set of tests selected for identifying the *Vibrio* species obtained from the cultures of bivalve mollusks in Galicia are simi-

lar to those previously reported by other authors (West et al. 1986; Pujalte et al. 1993; Alsina & Blanch 1994a, Cerdá-Cuéllar et al. 1997, Thyssen et al. 1998, Zorrilla et al. 1999).

We have identified a single isolate of *Ph. damsela* subsp. *piscicida*, a causative agent of pasteurellosis (Zorrilla et al. 1999), associated with water samples (see Table 3). Also, *V. (Listonella) anguillarum*, a pathogen for fish, shellfish, bivalve mollusks, and other marine animals (Farmer & Hickman Brenner 1992), was isolated from oyster larvae and reproductive oysters. Nevertheless, we could detect neither *V. tubiashii*, a pathogen of oysters and clams (Hada et al. 1984) nor *V. tapetis*, the causative agent of the brown ring disease in clams (Borrego et al. 1996). Although previously associated with diseased wild octopus in NW of Spain (Farto et al. 2003), in our study, undertaken in the same area, *V. lentus* could not be isolated from bivalve mollusks cultures. *V. alginolyticus*, a potential pathogen for humans and shellfish, was isolated from clam larvae and seeds and reproductive oysters. The pathogens *V. vulnificus* and *V. parahaemolyticus* were not detected, even though they are common inhabitants of estuarine and marine environments and are frequently isolated from seawater and seafood (Maugeri et al. 2000). This concurs with the results of studies undertaken on oysters from the Mediterranean Sea (Ortí-gosa et al. 1994a, Pujalte et al. 1999), but contrasts with the abundance of these species in oysters from other geographical areas, such as the United States (O'Neill et al. 1990, Hlady et al. 1993, Wright et al. 1996) or Japan (Hor et al. 1995). The human pathogens *V. fluvialis* and *V. metschnikovii* were not detected. However, 43% of aerobic strains and 41% of facultative anaerobic strains remain unidentified.

In phenon 37 (see Fig. 2), seven facultative anaerobic isolates, associated with the reproductive stage in clams, showed a different identification depending on the data matrix used: they were iden-

tified as *Plesiomonas shigelloides* using the matrix of Bryant et al. (1986), or as *Photobacterium phosphoreum* according to that of Alsina and Blanch (1994a). The probability level of being one or the other species was very high, 98%, for both species. It was not possible to differentiate between these two species with the 92 tests used in this study. More standard tests and molecular techniques should be included for a definite confirmation.

This is not an ecological study about variability through time, but the high number of strains we have isolated from bivalve mollusks cultures in different geographical areas during a long time period, as well as the method we have used to obtain them, gives these isolates a representative value of the most frequent culturable bacteria associated with the culture of bivalve mollusks in the NW of Spain.

Numerical taxonomy is a well-accepted method to search for differential phenotypic characteristics among close taxonomic strains. This allows a rapid presumptive identification that is very useful in diagnostics and sanitation control analyses.

All discriminatory tests are presented to provide a rapid presumptive guide for identifying environmental and the most frequent pathogenic bacterial isolates from cultures of Galician bivalve mollusks. This guide has proved to be very useful for differentiating the high bacterial variability that we have found in this study.

ACKNOWLEDGMENTS

This work was supported by grants PGIDIT00MAR2002PR and PGIDIT02RMA30102PR from the *Xunta de Galicia*. The authors thank J. Montes and CECT for the kind provision of bacterial isolates and reference strains respectively, and also E. Longo for providing the multipoint inoculator.

ABSTRACT To estimate the abundance of scallop populations either by VPA approach or by directed survey on seabeds it is necessary to evaluate the efficiency of fishing gears. The age-size structure of commercial or experimental catches does not usually correspond to that of the targeted population. Several previous studies on scallop stocks in Scottish or English Channel waters show that different functions can be fitted on relationships of dredge efficiency versus scallop size (monotonic increasing functions or curves including increasing and decreasing stages). The two ways to tackle the question involve to calculate efficiency estimates, absolute (by diving after dredge haul) or relative (by comparing two different parameter dredges in standardized sampling conditions). This study develops aspects of methodology applied on calculation of dredge efficiency parameters. The study focuses on data of English Channel French scallop fisheries.

KEY WORDS: scallop, dredge, depressor plate, efficiency, logistical curve, variance, Taylor's polynomial

INTRODUCTION

In the assessment of the abundance and biomass of scallop populations, there is a requirement to calculate the efficiency and selectivity of the fishing gear. An extrapolation has to be made because age-size composition of commercial or experimental catches does not correspond to that of the actual population. A multiplicative factor including tow components has to be taken into account: (1) the first component is a correction rate independent of scallop size because only a part of the individuals are retained by dredging and (2) the second factor depends on size because of selectivity component through meshes and tooth spacing (Dare et al. 1993, Fifas & Berthou 1999).

After several recommendations for general methodology, we report on an evaluation of dredge efficiency experiment either using divers (Saint Brieuc Bay, Western English Channel; Fig. 1) or using two different mesh size dredges (Bay of Seine; Eastern English Channel; see Fig 1). In both cases, the experimental fishing gears are dredges fitted with a depressor plate (Fig. 2) and equipped with a belly and back ring size of 50 mm.

In the first case, the estimator is called absolute efficiency written as (Laurec & Le Guen 1981, Buestel et al. 1985):

$$\text{absolute efficiency} = \frac{\text{number of scallops in the dredge}}{\text{total number of scallops (dredge + sea bottom)}} \quad (1)$$

In the second case, we usually compare two different mesh size dredges (Vigneau et al. 2001). The experiment can also be performed between two types of vessels; Weinberg et al. (2000) compared swept area estimates of research and commercial vessels on catches of Atlantic surfclam (*Spisula solidissima*). The comparative estimator called relative efficiency is expressed by:

$$\text{relative efficiency} = \frac{\text{number of scallops in the first dredge (or vessel)}}{\text{number of scallops in the second dredge (or vessel)}} \quad (2)$$

Components of Efficiency

Dickie (1955), Dupouy (1982), and Dare & Palmer (1994) calculated dredge efficiency by tagging/recapture of scallops. Chapman et al. (1977) and Mason et al. (1979) worked on standard and spring-loaded dredges by using divers to survey the track after dredging; the same approach was also developed on dredges with depressor plate by Buestel et al. (1985); Beukers-Stewart et al. (2001) estimated absolute and relative efficiency of spring-loaded dredges. Similar studies were conducted on other species (e.g. oysters: *Ostrea luaria*, Allen & Cranfield 1979; *Tiostrea chilensis*, Doonan et al. 1994; black scallop, *Chlamys varia*: Shafee 1979; blue crab, *Callinectes sapidus*: Zhang et al. 1993; Voelstad et al. 2000; blue mussel, *Mytilus edulis*: Dolmer et al. 1999). Fifas (1991) and Fifas and Berthou (1999) also adopted the diving method for European scallops and argued that dredge efficiency in the case of fishing gear equipped with depressor plate can often be fitted by increasing monotonic curves (logistical equation).

Components of dredge efficiency were listed by Dare et al. (1993) for spring-loaded gears and by Vigneau et al. (2001) for gears with depressor plate. This review is completed by Horton (personal communication):

- (1) Combination of vessel speed/warp length: combination of both parameters exert influence on dredge towing tension: to stabilize towing efficiency, the higher dredging speed the longer warp (e.g. warp length is usually equal to three times depth for a dredging speed of three knots).
- (2) Water depth: Water depth potentially introduces an auxiliary variable of efficiency related to warp weight (depending on warp diameter and material) even if warp length is optimized against vessel speed. Potentially an increase of water depth reduces dredge penetration in sediment because the force exerted on warp in traction is the resulting vector of towing traction and warp weight (warp buoyancy can be neglected).
- (3) Direction of tow in relation to tidal flow: experience of commercial skippers confirmed by diving operations during scientific surveys emphasizes the effect of tow direction against tide: it was conclusively proved that the direc-

Figure 1. The main scallop fisheries of the area studied: the Saint-Brieuc Bay and the Bay of Seine in the English Channel.

tion of tow has to be directed against the tidal current of weak or mean coefficient (e.g. less than 90 in the Western English Channel) to reduce random variations of dredge efficiency.

- (4) Compression of tooth bar spring (spring-loaded dredges): Fishermen modify the spring extension according to empirical observations of catch and dredge behavior. They try different spring tensions on each dredge on a given seabed type until dredges start to catch scallops and then adjust the springs of the other dredges to be the same as the one that is catching optimally. Skippers also use other clues to dredge functioning: vibrations through the warps, wear on the teeth and other parts of the dredge and quantity of stones caught. Compressed spring are considered more adequate on flat substrates (the tooth angle is constant and the fishing gear penetrates in the sediment) whereas extended one is more efficient on rougher seabed (the tooth angle is variable and the dredge is able to fish among rocks and sandbanks). However, the approach varies between skippers.
- (5) Inclination of pressure plate (dredges with depressor plate): The depressor plate has two roles: to increase the stability of the dredge on the seabed and potentially to facilitate entry of material in the dredge bag owing to deflection of water at the entrance to the dredge. Too inclined pressure plate may create water turbulence that obstructs entry of scallops in the bag (Baird 1957).
- (6) Tooth length and spacing: Baird (1957) underlined the role of dredge teeth not only on scallop selection, but also on by-catch quantities and substrate fragments. In Fifas and Berthou (1999), tooth length of an experimental dredge was varied according to the nature of the sediment: for soft sea bottom, tooth length is 130 mm, and, for rough sea bottom, the length is 90 mm. Shorter length and reduced spacing results in more rapid filling up of the dredge bag with catch and by-catch. Lart (2003) found that tooth spacing affected selectivity in spring toothed dredges.
- (7) Mesh back size and material: Dupouy (1982), found that dredge efficiency on large scallops increased with increased mesh size (a 9% increase for mesh size of 90 mm compared with of 72 mm). In addition to a selectivity pro-

cess, a decrease in mesh size has the potential to modify the efficiency component independent of scallop size because of a reduction of hydrodynamic flow through the meshes.

- (8) Sediment type: apart from influence of seabed topography (rocks reefs and flat sea bottom; see # 4 earlier), substrate nature (sand, mud, gravels, and rocks) determines dredge efficiency (Laurec & Le Guen 1981). In Saint-Brieuc Bay, Buestel et al. (1985) estimated that efficiency of dredge with depressor plate at almost 0.67 on a soft sea bottom whereas it was equal to 0.30 on a rough seabed.
- (9) Tow duration and hence distance covered: It can be inferred from numbers 6 and 7 in this list that tow duration has to be adapted to avoid overfilling the dredge. This would explain Shafee's (1979) observation of a reduction of efficiency with increased haul duration for black scallop beds.
- (10) Population density: Zhang et al. (1993) report that dredge efficiency seems to have declined exponentially as blue crab density increased.

Matrix of Components

Among components listed above, we can neglect each independent variable that can be explained by another one. For example: (1) A combination of direction of tow, water depth and warp weight allows to calculate towing tension on sea bottom against observations at the surface; (2) biologic experiments can always be conducted against the tidal flow and during periods that do not generally exceed mean level coefficients to minimize as much as possible random variations of efficiency estimates; (3) the influence of mesh material can be neglected because the use of metal rings for the whole dredge back is generalized for the main French scallop fisheries; (4) sampling of scallop beds are usually carried out on heavily exploited populations where densities are likely to be low and thus components related to population density need not be taken into account.

After those simplifications, a square correlation matrix between efficiency parameters can be proposed at the aim of stabilizing efficiency value when a parameter is modified. The example cited in this study concerns spring-loaded dredges (Table 1).

Experiments carried out on dredge efficiency aim to eliminate the maximum number of parameters (by modeling, ANOVA or bootstrapping) that can be expressed by each other; only parameters with low correlations are of significant interest for analysis to avoid collinearity artefacts.

Figure 2. The experimental fishing gear. A dredge with a depressor (diving) plate.

TABLE I.

Square matrix of correlations between efficiency parameters. Example of spring-loaded dredges.

	Warp Tension	Spring Compression	Tooth Length	Tooth Spacing	Mesh Size	Sediment Type
Warp tension	1	0	???	0	0	0
Spring compression	0	1	???	???	???	F(X)
Tooth length	???	???	1	—	—	—
Tooth spacing	0	???	—	1	—	0
Mesh size	0	???	—	—	1	???
Sediment type	0	F(X)	—	0	???	1

0 = absence of correlation; 1 = collinearity; ??? = unknown (no experiment report); — = negative unknown value; F(X) = one of both parameters experimentally adjusted against the second one.

MATERIALS AND METHODS

Monotonic Functions for Dredges with Depressor Plate

The numerical examples reported in this study involve the analysis of the efficiency of dredges with depressor plate. In this particular dredge pattern, some simplifications are to be considered: compression does not exist while tooth angle and depth of teeth in sea bottom are reduced to only one independent variable (i.e. tooth length). An analysis of influence of tooth length is developed.

Previous studies (Buestel et al. 1985, Fifas 1991, Fifas & Berthou 1999, Vigneau et al. 2001) on scallop French fisheries (tooth length of 90–130 mm according to nature of the sea bottom) argued that experimental dredge efficiency, either absolute or relative, is explained by monotonic function versus scallop size (Fig. 3a and Fig. 3b). The same trends have been observed in the case of commercial dredges in Brittany (see Fig. 3c). Fifas and Berthou (1999) pointed out that efficiency is made up of the following coefficients:

- (1) A certain number of small sized scallops can escape through the 50 mm rings: this phenomenon defines the selectivity of dredge mesh related to escaping capacities of scallops that decrease as individual size increases.
- (2) Nevertheless, scallop dredges present a second type of selectivity, namely through the teeth that can be called the selectivity of the toothed bar. On the one hand, this phenomenon is similar to selectivity through the rings and can be described by an increasing monotonic function of the scallop size, but, on the other hand, it depends on the mechanical and physical conditions of dredging (e.g., the setting of the dredge due to the tooth length, meteorological conditions, etc.). This two-stage selection and retention process (by toothed bar and meshes) has already been described in the case of spring-loaded dredges (Dare et al. 1993 and Lart 2003).
- (3) A final component of efficiency is related to the mechanical and physical characteristics of dredging that are independent of scallop size. Even when individuals attain a large size and cannot escape through the teeth or the rings, all scallops are not caught on a dredged area: a certain number of them are still left on the bottom. This third term is defined as efficiency depending on the physical (nature of sea bottom, direction and speed of winds and currents, etc.) and mechanical (speed and direction of ship during the dredging, etc.) characteristics. If we consider that these

different parameters have a residual effect during stock assessment, we assume that, unlike the first two components of efficiency, the physical and mechanical components can be represented by a constant.

In regards to components as indicated earlier it is concluded that only one biologic component is included in usual efficiency models: this component is associated with escaping capacity of scallops and explains monotonic feature of efficiency against size.

In this case, absolute efficiency is represented by logistical functions (Fifas & Berthou 1999):

$$e_i = \frac{e_{\max}}{1 + \exp[-\alpha \cdot (L_i - L_{50})]} + \xi_i \quad (3)$$

with:

e_{\max} = maximum asymptotical efficiency; this term is considered to be independent of scallop size; it depends on physical and mechanical characteristics during dredging.

α = parameter linked to the deviation of selection of experimental dredge, defined by the difference $L_{75} - L_{25}$ of scallop sizes where efficiency is equal to 75% and 25%, respectively, of maximum asymptotical efficiency [$\alpha = 2 \cdot \ln(3) / (L_{75} - L_{25})$].

L_{50} = size corresponding to 50% of the maximum asymptotical efficiency.

ξ_i = unexplained residual error.

For a size L_i , the observed efficiency, e_i , is written as:

$$e_i = \frac{N_{i1}}{N_{i1} + N_{i2}} \quad (4)$$

where:

N_{i1} and N_{i2} = number of individuals of size L_i , caught by the dredge and those left on the sea bottom, respectively.

Furthermore, relative efficiency is a ratio of two logistical curves expressed by (Vigneau et al. 2001):

$$e_i = C \cdot \frac{1 + \exp[-\alpha' \cdot (L_i - L'_{50})]}{1 + \exp[-\alpha \cdot (L_i - L_{50})]} + \xi_i \quad (5)$$

where:

C = ratio of the two maximum asymptotical efficiencies ($C = e_{\max} / e'_{\max}$); the terms e_{\max} , e'_{\max} for the two mesh sizes (72 and 50 mm respectively) are considered according to assumptions above, see formula (3).

α and α' = parameters linked to the deviation of selection of experimental dredges for the two mesh sizes (72 and 50 mm respectively) defined as in equation (3).

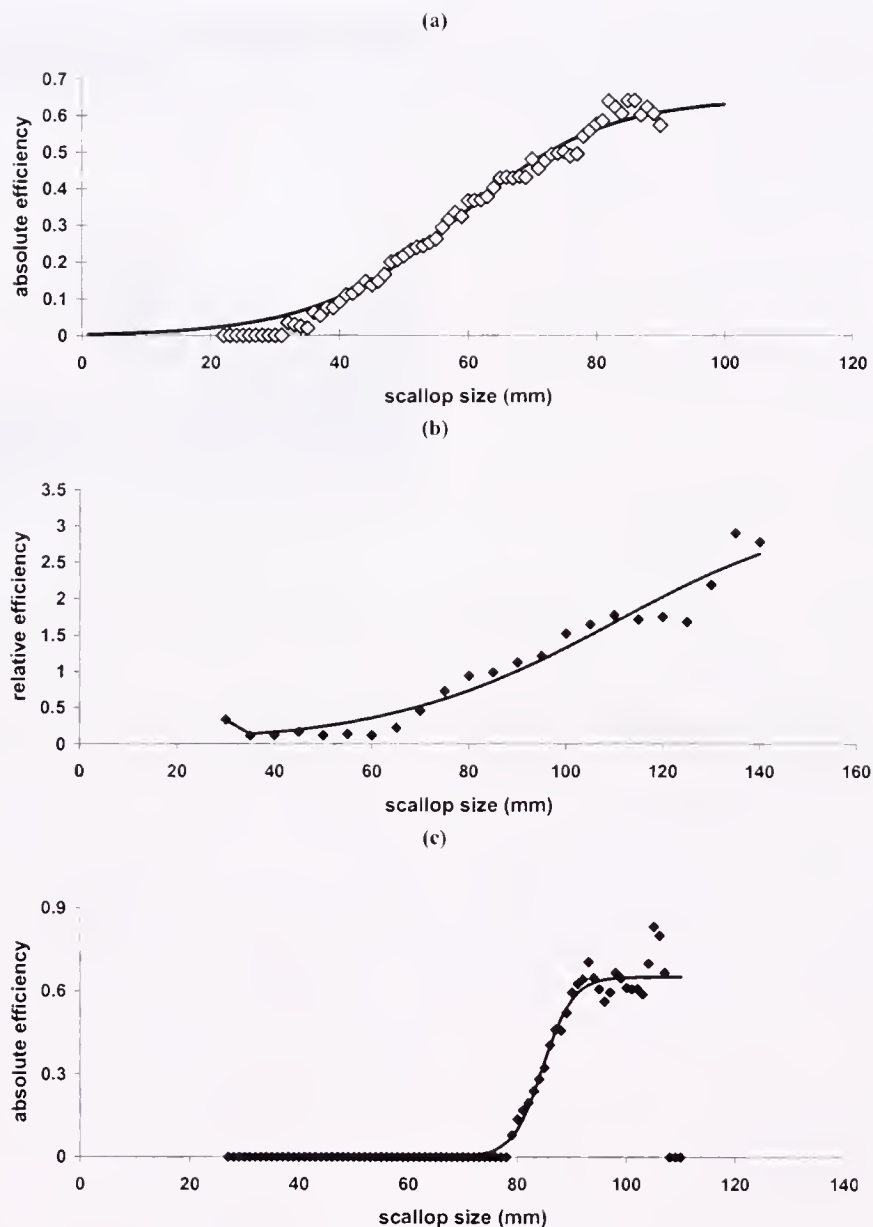

Figure 3. Previous studies on efficiency estimates of scallop dredges. (a) Absolute efficiency of experimental dredge in Saint-Brieuc Bay (mesh size of 50 mm; in Fifas and Berthon, 1999). (b) Relative efficiency of experimental dredges in Bay of Seine (mesh sizes of 50 and 85 mm; in Vigneau et al., 2001). (c) Absolute efficiency of commercial dredges in Brittany (mesh size of 92 mm; unpublished data; $e_{\max} = 0.652$; $\alpha = 0.363$; $L_{50} = 84.685$).

L_{50} and L'_{50} = size corresponding to 50% of the maximum asymptotical efficiency (for the mesh sizes of 72 and 50 mm).

For a size L_i , the observed efficiency, e_i , is expressed by:

$$e_i = \frac{N_i}{N'_i} \quad (6)$$

where:

N_i and N'_i = numbers of individuals of size L_i , caught by the two dredges (mesh sizes of 72 and 50 mm).

Composite Functions

The simplified modeling script of only one biologic component involving monotonic functions of efficiency is not always veri-

fied in experimental surveys. Sometimes, as described by Mason et al. (1979) on Scottish scallop fisheries exploited by spring-loaded dredges, a double model better describes efficiency versus size: one increasing function as logistic equations cited earlier, another one linear decreasing. Experimental data sampled during 1990s using dredges with depressor plate on scallop fisheries of the Western English Channel (tooth length of 75 mm) have revealed the same aspect: decreasing efficiency seems to start above a limiting size of 90–100 mm (see experimental data in Fig. 4). Only mathematical estimators of absolute efficiency will be presented later. A two-stage efficiency model can be expressed as:

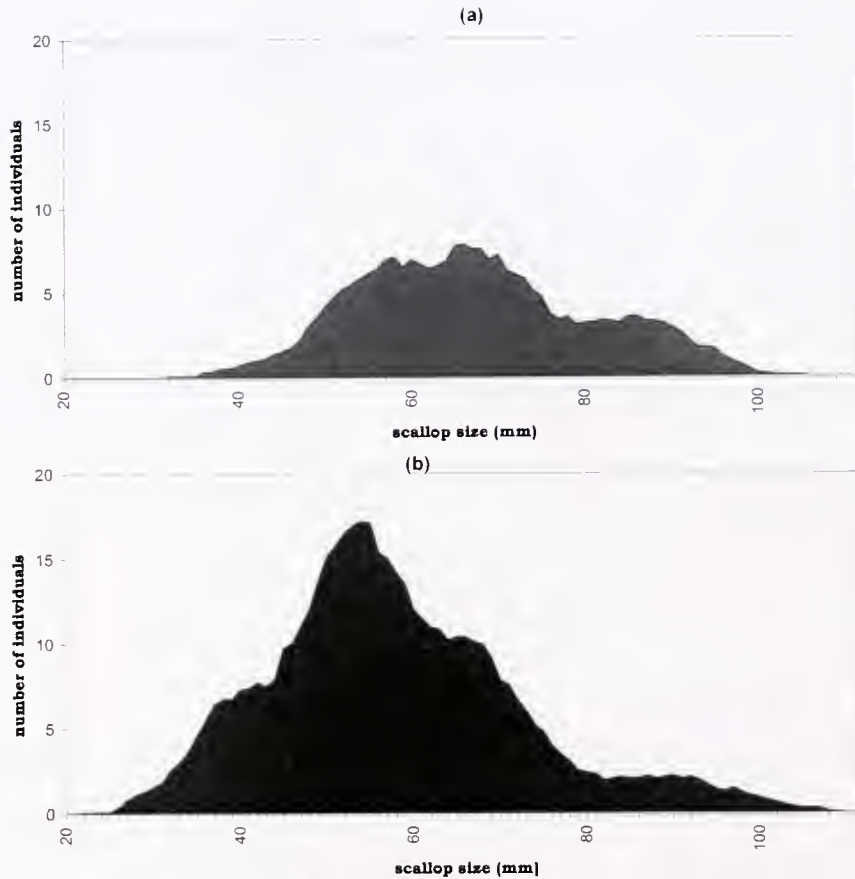

Figure 4. Distribution of size frequencies of scallops used in experiments: (a) Scallops caught by experimental dredges. (b) Escaping scallops harvested by diving on dredge track.

$$e_i = \frac{e_{\max}}{1 + \exp[-\alpha \cdot (L_i - L_{50})]} + \xi_i \quad \text{if } L_i \leq L_{\lim} \quad (\text{increasing logistical stage})$$

$$e_i = C \cdot \exp[-b \cdot L_i] + \xi_i \quad \text{if } L_i \geq L_{\lim} \quad (\text{decreasing exponential stage}) \quad (7)$$

Note: if b approaches zero, $C \cdot \exp[-b \cdot (L_i - L_{\lim})] \approx C \cdot [1 - b \cdot (L_i - L_{\lim})]$ and decreasing stage of efficiency against size is close to linear one described by Mason et al. (1979).

If the two stages of the model must give the same fitted value of efficiency for the limit size L_{\lim} , it is concluded that:

$$C = \frac{e_{\max} \cdot \exp[b \cdot L_{\lim}]}{1 + \exp[-\alpha \cdot (L_{\lim} - L_{50})]} \quad (8)$$

which reduces the number of unknown parameters of the efficiency model to five from six. Thus, the formula (7) can be written:

$$e_i = \frac{e_{\max}}{1 + \exp[-\alpha \cdot (L_i - L_{50})]} + \xi_i \quad \text{if } L_i \leq L_{\lim}$$

$$e_i = \frac{e_{\max} \cdot \exp[-b \cdot (L_i - L_{\lim})]}{1 + \exp[-\alpha \cdot (L_{\lim} - L_{50})]} + \xi_i \quad \text{if } L_i > L_{\lim} \quad (9)$$

For the fitting of the two-stage model different algorithms can be performed based on parametric approaches (e.g., conditional maximum likelihood model: Millar 1991; multinomial likelihood method: Perez-Comas & Skalski 1996) or on non-parametric ones

(e.g., Simplex method: Nelder & Mead 1965; complex method with constraint: Box, 1965). A comparison of direct and linear fitting methods was presented by Caddy and Defoe (1996). The fitting of the two-stage model has been conducted according to following principles:

- (1) The fitting has been done using Solver method of generalized reduced gradient, based on Newton's cancellation of the gradient (Waren & Lasdon 1979, Lasdon & Waren 1980, Lasdon & Waren 1983). Estimates of this parametric method were compared with those obtained by the Box (1965) non-parametric constrained estimation called Complex (including two constraints: $e_{\max} < 1$ and $L_{50} < L_{\lim}$).
- (2) The algorithm proceeds by minimizing the sum of the weighed residual squares: for a given size classe i , weight is equal to the corresponding total number of scallops, (i.e., scallops harvested by dredge) (N_{i1}), plus those sampled on the sea bottom by divers (N_{i2}). This procedure attributes greater weight to intermediate scallop size classes and probably reduces uncertainty in parameters α and L_{50} . The vector of parameters (e_{\max} , α , L_{50} , L_{\lim} , b) is estimated by minimizing the following quantity:

$$\sum_{i=1}^{nl} (N_{i1} + N_{i2}) \cdot \left[e_i - \frac{e_{\max}}{1 + \exp[-\alpha \cdot (L_i - L_{50})]} \right]^2 + \sum_{i=nl+1}^{nc} (N_{i1} + N_{i2}) \cdot \left[e_i - \frac{e_{\max} \cdot \exp[-b \cdot (L_i - L_{\lim})]}{1 + \exp[-\alpha \cdot (L_{\lim} - L_{50})]} \right]^2 \quad (10)$$

where: nc = total number of size classes taken into account for fitting; nl = number of size classes for $L_i \leq L_{lim}$.

Matrix of Variance-Covariance of Parameters

The Generalized Reduced Gradient and the Complex method do not give an estimate of the matrix of variances-covariances of the five parameters. In this case, it is usually recommended to apply non-parametric techniques such as the bootstrap method (Caddy & Defoe 1996). The calculation can also be carried out according to parametric procedure (Lin 1987, Fifas 1991) using Jacobian matrix (i.e., matrix of partial derivatives of the objective).

The matrix of variances-covariances is obtained by the following relationship:

$$[M] = s^2 \cdot [I]^{-1} \quad (11)$$

with:

$[M]$ = matrix of variances-covariances; $[I]^{-1}$ = inverse of matrix of information; s^2 = sum of mean residual squares of the fitted function:

$$s^2 = \frac{\sum_{i=1}^{nl} \left[e_i - \frac{e_{max}}{1 + \exp[-\alpha \cdot (L_i - L_{50})]} \right]^2 + \sum_{i=nl+1}^{nc} \left[e_i - \frac{e_{max} \cdot \exp[-b \cdot (L_i - L_{lim})]}{1 + \exp[-\alpha \cdot (L_{lim} - L_{50})]} \right]^2}{nc - 5} \quad (12)$$

The matrix of information is obtained by:

$$[I] = [J]' \cdot [J] \quad (13)$$

$[J]$ is the Jacobian matrix (nc rows and 5 columns):

$$[J] = \begin{bmatrix} \frac{\partial e_1}{\partial e_{max}} & \frac{\partial e_1}{\partial \alpha} & \frac{\partial e_1}{\partial L_{50}} & \frac{\partial e_1}{\partial L_{lim}} & \frac{\partial e_1}{\partial b} \\ \frac{\partial e_2}{\partial e_{max}} & \frac{\partial e_2}{\partial \alpha} & \frac{\partial e_2}{\partial L_{50}} & \frac{\partial e_2}{\partial L_{lim}} & \frac{\partial e_2}{\partial b} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \frac{\partial e_{nc}}{\partial e_{max}} & \frac{\partial e_{nc}}{\partial \alpha} & \frac{\partial e_{nc}}{\partial L_{50}} & \frac{\partial e_{nc}}{\partial L_{lim}} & \frac{\partial e_{nc}}{\partial b} \end{bmatrix} \quad (14)$$

$[J]'$ is the transpose of $[J]$, the partial derivatives of the equation (14), also defined as absolute coefficients of sensitivity of order 1 written as $a(e_{max})$, $a(\alpha)$, $a(L_{50})$, $a(L_{lim})$ and $a(b)$, are presented in the annex 1 (formulae (18) to (22)) and the matrix of information $[I]$ is inverted using an algorithm presented by Lefebvre (1980).

The matrix of variances-covariances of the five parameters of the model and the use of partial derivatives of order 1 provide an approximate calculation of the variance of the variable $\Psi(L)$ corresponding to efficiency versus size L . This procedure is based on limited developments of order 1 in Taylor's series (called delta methods: Laurec 1986, Laurec & Mesnil 1987, Chevaillier 1990, Chevaillier & Laurec 1990, Fifas 1991).

By using Taylor's polynomial on a function Φ against parameters $\theta_1, \theta_2, \dots, \theta_k$ it is possible to present the variance of Φ by:

$$V[\Phi] \approx \sum_{i=1}^k \left(\frac{\partial \Phi}{\partial \theta_i} \right)^2 \cdot V[\theta_i] + 2 \cdot \sum_{i=1}^{k-1} \sum_{j=i+1}^k \frac{\partial \Phi}{\partial \theta_i} \cdot \frac{\partial \Phi}{\partial \theta_j} \cdot \text{Cov}[\theta_i, \theta_j] \quad (15)$$

In the case of the efficiency two-stage model, the formula (15) is equivalent to:

$$\begin{aligned} V[\Psi(L)] \approx & \left(\frac{\partial \Psi(L)}{\partial e_{max}} \right)^2 \cdot V[e_{max}] + \left(\frac{\partial \Psi(L)}{\partial \alpha} \right)^2 \cdot V[\alpha] \\ & + \left(\frac{\partial \Psi(L)}{\partial L_{50}} \right)^2 \cdot V[L_{50}] + \left(\frac{\partial \Psi(L)}{\partial L_{lim}} \right)^2 \cdot V[L_{lim}] \\ & + \left(\frac{\partial \Psi(L)}{\partial b} \right)^2 \cdot V[b] + 2 \cdot \frac{\partial \Psi(L)}{\partial e_{max}} \cdot \frac{\partial \Psi(L)}{\partial \alpha} \cdot \text{Cov}[e_{max}, \alpha] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial e_{max}} \cdot \frac{\partial \Psi(L)}{\partial L_{50}} \cdot \text{Cov}[e_{max}, L_{50}] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial \alpha} \cdot \frac{\partial \Psi(L)}{\partial L_{50}} \cdot \text{Cov}[\alpha, L_{50}] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial e_{max}} \cdot \frac{\partial \Psi(L)}{\partial L_{lim}} \cdot \text{Cov}[e_{max}, L_{lim}] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial e_{max}} \cdot \frac{\partial \Psi(L)}{\partial b} \cdot \text{Cov}[e_{max}, b] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial \alpha} \cdot \frac{\partial \Psi(L)}{\partial L_{lim}} \cdot \text{Cov}[\alpha, L_{lim}] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial \alpha} \cdot \frac{\partial \Psi(L)}{\partial b} \cdot \text{Cov}[\alpha, b] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial L_{50}} \cdot \frac{\partial \Psi(L)}{\partial L_{lim}} \cdot \text{Cov}[L_{50}, L_{lim}] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial L_{50}} \cdot \frac{\partial \Psi(L)}{\partial b} \cdot \text{Cov}[L_{50}, b] \\ & + 2 \cdot \frac{\partial \Psi(L)}{\partial L_{lim}} \cdot \frac{\partial \Psi(L)}{\partial b} \cdot \text{Cov}[L_{lim}, b] \end{aligned} \quad (16)$$

RESULTS

The results of fitting are presented in Table 2 that also provides the main parameters of the logistic curve fitted for increasing stage (deviation of selection, factor of selection) and the matrix of variances-covariances and of correlations between the parameters. The fitted efficiency model with mean confidence intervals (see calculation of variance in formula [16]) is given in Figure 5. Variance of efficiency calculated by using Taylor's polynomial is illustrated versus scallop size in Figure 6; absolute coefficients of sensitivity of order 1 for the 5 model parameters are given by Figure 7.

The estimated relationship of efficiency e_i against size L_i is written as:

$$\begin{aligned} e_i &= \frac{0.629}{1 + \exp[-0.095 \cdot (L_i - 57.824)]} & \text{if } L_i \leq 92.478 \\ e_i &= 0.607 \cdot \exp[-0.168 \cdot (L_i - 92.478)] & \text{if } L_i > 92.478 \end{aligned} \quad (17)$$

A general examination of the fitted function shows that the chosen two-stage model is well adopted. In fact, the maximum asymptotical value, e_{max} , of the increasing logistical stage equal to 0.629 is close to that of previous studies on the same area for large sized scallops: Buestel et al. (1985) estimated this value at 0.7. Furthermore, Fifas (1991) used a ratio estimator for scallops of age-group 3 and plus (including individuals larger than 80 to 90 mm) of 0.675 and Fifas and Berthou (1999) calculated a maximum asymptotical efficiency of 0.646. Thus, it is indicated indirectly that asymptotical efficiency level is independent of depth of toothed bar in the ground because all experiments cited earlier were undertaken with

TABLE 2.
Fitting of the two-stage function of efficiency.

Parameter	Value	Standard Deviation	C.V. (%)
e_{\max}	0.629	0.026	4.192
α (mm ⁻¹)	0.095	0.009	9.754
L_{50} (mm)	57.824	1.431	2.475
L_{\lim} (mm)	92.478	0.089	0.096
b (mm ⁻¹)	0.168	0.022	13.318

factor of selection: $L_{50}/L_{\text{mesh}}(50) = 1.156$
deviation of selection: $2.\ln(3)/\alpha = 23.015$ mm

	e_{\max}	α	L_{50}	L_{\lim}	b
Matrix of Variances-Covariances					
e_{\max}	0.696E-03	-0.188E-03	0.326E-01	-0.764E-03	0.000

various tooth length. In regards to unpublished fitted model for commercial dredge efficiency (see Fig. 3c), e_{\max} is also independent of mesh size (commercial dredges are equipped with 92 mm size, and biologic experiments are led with 50 mm meshes whereas both asymptotical levels are close); on this point, it is still difficult to conclude because observations on commercial efficiency have been carried out on only one vessel and fishing fleet variability is neglected.

In the same, comparison of the other parameters associated with the increasing stage of the model (α and L_{50}) reveals weak differences from equivalent values of monotonic functions (0.095 and 57.824 against 0.088 and 58.620, respectively, proposed by Fifas & Berthou [1999]) when only experimental dredge mesh size (50 mm) is considered. The most significant difference from pre-

vious results consists on existence of a decreasing stage similar to Mason et al. (1979) even if those authors proposed a linear model for the second stage. It is necessary to determine which is the design characteristic inducing the absence of asymptotical level on the efficiency curve. Most of the equipment of experimental dredges used by Fifas and Berthou (1999) and by this study were identical (dredge width, mesh size and material, tooth spacing, and inclination of the depressor plate); both dredges were also towed by the same vessel in similar meteorologic and tidal conditions. The difference in design designs consisted of differences in tooth length: 75 mm in this work against 90–130 mm used by Fifas and Berthou (1999) according to nature of the sea bed (soft or rough).

DISCUSSION

Physical and Biological Interpretation

In accordance with Baird (1957), use of short teeth on dredge bar modifies scallop selection and also quantity of non target spe-

Figure 5. The fitted two-stage efficiency model with confidence intervals (confidence level $1-\alpha = 0.95$).

cies and substrate fragments. Other works discuss a combination of engineering and biologic approach on dredge design and gear efficiency (Cover & Sterling 1994 and Gaspar et al. 1999). A less penetration in the sediment, due to tooth length, causes a quicker filling up of the dredge bag. When filling up level is reached, hydrodynamic forces exerted through the meshes are significantly reduced and filtering capacities of dredge are minimized. A cylindrical strip of sediment is formed at the front of the dredge and obstructs entry of solid material in the bag. Hence, this implies decrease of forces leading scallops and by-catches into the dredge bag.

Thereby, beside the three components of efficiency models described by Fifas and Berthou (1999) (i.e., selectivity of bag meshes, selectivity of the toothed bar, maximum asymptotic level related to mechanical and physical characteristics of dredging), a fourth one (depletion of dredge efficiency after filling up in the case of short tooth length) has to be taken into account in agreement with Mason et al. (1979). Breaking of efficiency increasing stage seems to occur suddenly at a given scallop size (i.e., at a given weight: reduced hydrodynamic forces through meshes are probably not enough to attract heavier material (e.g., for 75 mm of tooth length, limit scallop size is equal to 92 mm i.e., almost 140 g of individual weight). Decreasing second stage of the curve against scallop size can be interpreted by 3 factors:

(1) Physical factor, resulting force from antagonism between scallop weight (increasing vs. size) and attractive component inward dredge bag (decreasing as and when filling up) is reduced; (2) Passive behavior factor, if dredge teeth are short, large scallops are probably more able to avoid dredges passively because of deeper digging in the sediment (i.e., masking their upper valve with sand). Sakurai and Seto (2000) found that behavior of Japanese scallops *Patinopecten yessoensis* depends on size while recessing by coating themselves with sand in depression; (3) active behavior factor, Scallop swim by clapping valves and water ejected from the mantle cavity during closing of the valves generates thrust that propels the animal. Many authors (Moore & Trueman 1971, Gruffydd 1976, Chapman 1981, Joll 1989, Dadswell & Weihs 1990, DeMont 1990, Arsenault & Himmelman

1996, Cheng & DeMont 1996, Fleury et al. 1996, Arsenault et al. 1997, and Sakurai & Seto 2000) debated on size-related swimming pattern of various pectinid species. In spite of differences between locomotion abilities of those species (e.g., *Amusium balloti* or *Chlamys islandica* do longer displacements than *Pecten maximus*), a common point emerges: small individuals swim more often, but effectiveness of movements caused by environmental disturbance grows with size.

Statistical Consequences of the Two-stage Model

The analysis of absolute coefficients of sensitivity for the efficiency one-stage model proposed by Fifas and Berthou (1999) was carried on three parameters, e_{\max} , α and L_{50} . These coefficients approach 0 asymptotically apart from the parameter e_{\max} close to 1 when scallop size L approaches $+\infty$. In the case of the two-stage model of this work, all sensitivity coefficients approach 0 because e_{\max} does not have the same sense: it is just a theoretical maximum value of the dredge efficiency for a narrow size interval near L_{\lim} . This is the main disadvantage due to the model discontinuity around L_{\lim} .

The coefficient $a(e_{\max})$ is represented by a curve close to fitted function. This fact indicates that for a given absolute error of e_{\max} , the error of the dependent variable (efficiency) increases for sizes below L_{\lim} , decreases for upper values.

The coefficients $a(\alpha)$ and $a(L_{50})$ are given by functions close to those investigated by Fifas and Berthou (1999), a non-symmetrical periodic function for the first one, a symmetrical at around L_{50} for the second. For the intermediate size range, the absolute errors of α or L_{50} contribute less significantly to the efficiency error. In the particular case of $L = L_{50}$, absolute error of α has a null contribution whereas negative effect of an absolute error of L_{50} is maximized.

The coefficient $a(L_{\lim})$ is maximized for $L = L_{\lim}$, then it declines exponentially. The maximum value is approximated by:

$$\frac{e_{\max}}{1 + \exp(-\alpha(L_{\lim} - L_{50}))} \quad (18)$$

(if we consider that α can be neglected comparatively to 1; see equation [21b]). In the scallop fishery of the Saint-Brieuc Bay, the contribution of an absolute error of L_{lim} is maximized for the frequently represented size classes around L_{lim} (90–100 mm).

The coefficient a (b) reaches its highest level for $L = L_{lim} + 1/b$ which is located in the same interval than above (90–100 mm), after that it converges slowly. As for L_{50} , the effect of an error of b is always negative.

Combined values of all those sensitivity coefficients with calculated variance-covariance parameters give a function of variance that does not have mathematically simple analytic formulation. It is characterized by 3 stages: (1) slow monotonical increase below L_{lim} (contribution of error of e_{max} grows to the detriment of α and L_{50}); (2) a very high peak for $L = L_{lim}$ (part of error of L_{lim} minimizes contribution of other four parameters) and (3) a decreasing stage for upper sizes (dominance of error of b). This investigation shows that efficiency two-stage model is well adapted for undersized individuals, but its use for great classes is disadvantaged. On the one hand, very high value of variance for L_{lim} requires a high accuracy on estimate of this parameter, but its physical interpretation is not easy (see earlier); on the other hand, contribution of b for large scallops indicates low precision of dredge efficiency because this parameter is the least accurate (see Table 2).

CONCLUSION

The fitting of the efficiency model is statistically satisfactory because it gives parameter coefficients of variation less than 10% to 15%. The data have been harvested over several years and this fact reduces the effects of inter-annual variability of efficiency, but it is necessary to verify if seasonal variability can be neglected because data were sampled during the same season. It would also be important to complete study by application of re-sampling techniques (bootstrap and jackknife). These methods cannot be developed on the data of this work because of the lack of information about the matching of harvested scallops to a given sample. The examination of absolute sensitivities and the analysis of the function of variance show the dominant role of the two parameters associated with the decreasing stage of the model. This point disadvantages efficiency models that are fitted on data collected by short toothed dredges because of reduction of accuracy of estimates for large scallop sizes. To assess scallop stocks by experimental surveys and to propose annual TAC, it is preferable to privilege stability of accuracy for as many scallop sizes as possible. Thus, it is better to use experimental dredges equipped by long tooth bars adapted according to nature of sea bottom. This

solution allows to calculate dredge efficiency characterized by relatively stable variance for exploited classes.

ANNEX 1

Partial derivatives of order 1 (absolute coefficients of sensitivity of order 1).

1. Parameter e_{max} :

$$a(e_{max}) = \frac{\partial e_i}{\partial e_{max}} = \frac{1}{1 + \exp[-\alpha \cdot (L_i - L_{50})]} \quad \text{if } L_i \leq L_{lim} \quad (19a)$$

$$a(e_{max}) = \frac{\partial e_i}{\partial e_{max}} = \frac{\exp[-b \cdot (L_i - L_{lim})]}{1 + \exp[-\alpha \cdot (L_{lim} - L_{50})]} \quad \text{if } L_i > L_{lim} \quad (19b)$$

2. Parameter α :

$$a(\alpha) = \frac{\partial e_i}{\partial \alpha} = \frac{e_{max} \cdot (L_i - L_{50}) \cdot \exp[\alpha \cdot (L_i - L_{50})]}{(1 + \exp[-\alpha \cdot (L_i - L_{50})])^2} \quad \text{if } L_i \leq L_{lim} \quad (20a)$$

$$a(\alpha) = \frac{\partial e_i}{\partial \alpha} = \frac{e_{max} \cdot (L_{lim} - L_{50}) \cdot \exp[-\alpha \cdot (L_{lim} - L_{50})] \cdot \exp[-b \cdot (L_i - L_{lim})]}{(1 + \exp[-\alpha \cdot (L_{lim} - L_{50})])^2} \quad \text{if } L_i > L_{lim} \quad (20b)$$

3. Parameter L_{50} :

$$a(L_{50}) = \frac{\partial e_i}{\partial L_{50}} = - \frac{\alpha \cdot e_{max} \cdot \exp[-\alpha \cdot (L_i - L_{50})]}{(1 + \exp[-\alpha \cdot (L_i - L_{50})])^2} \quad \text{if } L_i \leq L_{lim} \quad (21a)$$

$$a(L_{50}) = \frac{\partial e_i}{\partial L_{50}} = - \frac{\alpha \cdot e_{max} \cdot \exp[-\alpha \cdot (L_{lim} - L_{50})] \cdot \exp[-b \cdot (L_i - L_{lim})]}{(1 + \exp[-\alpha \cdot (L_{lim} - L_{50})])^2} \quad \text{if } L_i > L_{lim} \quad (21b)$$

4. Parameter L_{lim} :

$$a(L_{lim}) = \frac{\partial e_i}{\partial L_{lim}} = 0 \quad \text{if } L_i \leq L_{lim} \quad (22a)$$

$$a(L_{lim}) = \frac{\partial e_i}{\partial L_{lim}} = \frac{e_{max} \cdot \exp[-b \cdot (L_i - L_{lim})]}{1 + \exp[-\alpha \cdot (L_{lim} - L_{50})]} \cdot \frac{\alpha \cdot \exp[-\alpha \cdot (L_{lim} - L_{50})]}{1 + \exp[-\alpha \cdot (L_{lim} - L_{50})]} \quad \text{if } L_i > L_{lim} \quad (22b)$$

5. Parameter b :

$$a(b) = \frac{\partial e_i}{\partial b} = 0 \quad \text{if } L_i \leq L_{lim} \quad (23a)$$

$$a(b) = \frac{\partial e_i}{\partial b} = \frac{e_{max} \cdot (L_i - L_{lim}) \cdot \exp[-b \cdot (L_i - L_{lim})]}{1 + \exp[-\alpha \cdot (L_{lim} - L_{50})]} \quad \text{if } L_i > L_{lim} \quad (23b)$$

ENRICHMENT OF TETRANUCLEOTIDE MICROSATELLITE LOCI FROM INVERTEBRATE SPECIES

K. H. KAUKINEN,* K. J. SUPERNALUT AND K. M. MILLER

Department of Fisheries and Oceans Canada, Science Branch, Pacific Biological Station,
Nanaimo, B.C., Canada V9R 5K6

ABSTRACT An experimental procedure using biotin labelled probes and streptavidin bound magnetic beads was developed to produce microsatellite-enriched libraries in two bivalve species, geoduck and Japanese scallop, and one crustacean, Dungeness crab. Microsatellite libraries were enriched for GATA₃ and GACA₄ by 75–84%. The magnetic bead protocol produced genomic inserts ranging in size from 347–449 bp, with an average 5' and 3' flanking of 89–130 bp. Eight polymorphic loci were isolated from both geoduck clam and Dungeness crab. The heterozygosities ranged from 0.57–0.92 for Dungeness crab and 0.91–0.97 for geoduck. These novel polymorphic microsatellite loci will be useful in studying recruitment dynamics and genetic structure.

KEY WORDS: microsatellites, enrichment, magnetic beads, geoduck, crab, scallop

INTRODUCTION

Marine invertebrate species with pelagic larval stages should have tremendous capacity for dispersal and mixing over long distances. However, numerous studies have shown that over ecological time scales (10's of years), dispersal in many species is primarily local (Swearer et al. 2002). Even on evolutionary time scales (100's to millions of years), while the majority of marine invertebrate species with pelagic larvae do not contain a high degree of spatial structure at the 10–100+ km scale, there are some that do (e.g. Jiang et al. 1995; Burton 1998). Further, many studies have noted fine-scale heterogeneity among cohorts (termed chaotic genetic patchiness in Hellberg et al. 2002) that suggests (1) that few adults contribute to each recruitment event (Hedgecock 1994), or (2) that there is selection on genetic diversity in the larval stage (Johnson and Black 1984). Because effective management units must incorporate information on recruitment dynamics and genetic structure, it is imperative that these parameters are understood for species of economic importance and those of conservation concern.

For genetic analyses of population structure, numerous genetic markers have been utilised, including allozymes, mtDNA, minisatellites, microsatellites, and other coding and non-coding loci. Microsatellite loci, which are simple sequence repeats with 2 to 10 bp motifs organised in tandem arrays, are currently considered the marker of choice for determining the level of population connectedness over the span of 100's to 1000's of years. Microsatellite loci are often highly polymorphic due to a high rate of mutation through replication slippage, resulting in the gain or loss repeat units. In addition, microsatellite loci are as vulnerable to point mutations as the rest of the genome, which tends to divide longer repeat stretches into smaller units, and hence decrease the rate at which slippage occurs (Bell and Jurka 1997; Kruglyak et al. 1998). This "slippage/point-mutation" theory suggests that the frequency distribution of microsatellite lengths is a balance of expansion due to slippage and contraction due to point mutation (Sibly et al. 2003).

To date, all prokaryotic and eukaryotic genomes have been found to contain microsatellite loci. However, among eukaryote species, microsatellite repeats are more abundant and longer in vertebrates than invertebrates (Chambers and MacAvoy 2000). As

a result, many researchers have experienced difficulty in isolating microsatellite loci from marine invertebrate species, especially tetranucleotide repeat loci which are generally preferred for population studies due to their lack of stutter. In a study comparing the prevalence of di-, tri-, tetra- and hexanucleotide repeats in shrimp, Xu et al. (1999) found that only 9% of microsatellite loci were in the form of tetranucleotide repeats. Similarly, using traditional library screening methods, we probed red sea urchin (*Strongylocentrotus franciscanus*) libraries with ³²P-labelled (GACA) and (GATA) oligonucleotides, and less than 10% of the microsatellite sequences obtained were tetranucleotide repeats (Miller et al.). Moreover, most of the tetranucleotide containing loci were not sufficiently polymorphic for use in population studies or pedigree analyses.

Numerous methods advancing the techniques used in the isolation of microsatellites have been developed. The first microsatellite enrichment protocol was described by Ostrander et al. (1992) and later expanded by Paetkau (1999). Under their protocol, the fractionated DNA was packaged into a phagemid or phage vector and an ssDNA library was obtained. The ssDNA was used as a template for PCR using the repeated oligonucleotides as the primers, thus creating double stranded product enriched for repeats. Both methods were reviewed in Zane et al. (2002), but it was noted that only five primer papers to date have been accredited to these approaches.

Fischer and Bachmann (1998) and Hamilton et al. (1999) described magnetic bead methods of microsatellite enrichment. Both groups used a linker ligated to the restricted DNA fragments as a primer for PCR reactions. The adapter-linked DNA was then used as the target for 5' biotinylated repeat oligonucleotides and paramagnetic streptavidin beads. Both groups used genomic:oligonucleotide hybrids as the target for streptavidin magnetic beads. Fischer and Bachmann reported a greater than 60% enrichment of microsatellites in the onion plant *Allium cepa*, while Hamilton and colleagues reported a 20–95% enrichment rate. In their review, Zane et al. (2002) presented their own magnetic approach to microsatellite isolation termed FIASCO (Fast Isolation by AFLP of sequences containing repeats). In principle, the DNA was digested simultaneously with the AFLP adaptor to achieve a one-step digestion-ligation reaction. As above, the adapter linked DNA was used in a PCR step, hybridised with biotin-(AC)₁₇ and separated with streptavidin beads resulting in a 50–95% enrichment for dinucleotide repeat microsatellites.

The present study outlines the experimental procedure we developed to produce microsatellite-enriched libraries for marine invertebrate species. The magnetic bead enrichment approaches outlined above and in O'Reilly et al. (2000) form the basis of the methods developed, but substantial improvements were made to enhance the length of the core repeat and flanking sequence and the level of enrichment obtained. This procedure was applied in the development of highly polymorphic microsatellite loci from two gastropod species, geoduck (*Panopea abrupta*) and Japanese scallop (*Patinoplectin yessoensis*), and one crustacean species, Dungeness crab (*Cancer magister*). Primers to microsatellite loci for geoduck clams and Dungeness crab are described herein.

METHODS

Microsatellite enriched libraries were produced using magnetic bead hybridisation selection (Fig. 1). Genomic DNA was extracted from geoduck mantle, crab muscle, and scallop adductor muscle using a Stratagene DNA Extraction Kit (Stratagene, La Jolla, CA). Genomic DNA (approximately 50 µg) was partially digested with 10.8 U *Hae*III for 10, 20, and 30 min at 37°C. DNA fragments of 600–2000 bp were size selected and dephosphorylated by incubating 53 µl clean cut DNA with 10 U of CIP for 2 hr at 37°C. The CIP treated DNA was cleaned using spin columns (QIAquick PCR

purification kit, Qiagen, Valencia, CA) and eluted to a final volume of 60 µl in elution buffer.

The SNX linkers were designed according to Hamilton et al., 1999. Primers included SNX forward: 5'CTAAGGCCT-TGCTAGCAGAAGC3', and SNX reverse: 5'pGCTTCTGCTAG-CAAGGCCTTAGAAAA3'. The SNX linkers were added by PCR cycling in the presence of the SNX linkers, ligase and *Xmn*I. The ligation mixture contained 10 µl of CIP-treated DNA fragments, 3.9 mM mixed SNX reverse and forward, 1× Ligase Buffer, 1 U *Xmn*I and 2 U Ligase in a final volume of 30 µl. Ligations were cycled for 30' at 16°C, 10' at 37°C for 5–18 cycles, followed by 20' at 65°C to inactivate the enzymes, and then kept at 4°C. Different ligation cycling regimes were tested, and the optimum number of ligation cycles was empirically determined to be five. More than five cycles resulted in shorter fragments with multiple SNX linkers. The SNX ligation product was cleaned using spin columns and eluted to a final volume of 20 µl in EB.

The SNX PCR cocktail contained 0.8 mM SNX f, 0.8 mM dNTPs, 5 U Qiagen Taq, 2.5 mM MgCl₂, 10 µl SNX ligated DNA fragments, and 1× Qiagen PCR Buffer. The cycling protocol was 2' at 92°C followed by 40 cycles of 94°C/45", 62°C/1', 72°C/1', a final extension of 30'/72°C, and then held at 4°C. At this point, the PCR product can be immediately processed to the hybridisation step, size selected and concentrated, or cleaned with spin columns and retained for long-term storage. The ligation step can be tested by resolution on an agarose gel. A smear of products indicates a successful ligation and PCR.

All hybridisation steps were performed at 48°C in a controlled environment. All trays, tips, wash solutions and MPC (Molecular Particle Concentrator) were preheated to 48°C. Dynabead M-280 Streptavidin magnetic beads (DynaL ASA, Oslo, Norway) were washed 3 times with phosphate buffered saline with 0.1% sodium dodecyl sulphate using the Dynal MPC-S or -P (single or plate format) between washes. The beads were re-suspended in 5× SSC (20× SSC stock: 175.3g sodium chloride and 88.2g sodium citrate per litre; adjust pH to 7.0 with 10N hydrochloric acid). Previously, Hamilton et al. (1999) used genomic oligonucleotide hybrids as the target for streptavidin magnetic beads and O'Reilly et al. (2000) combined (GATA)₇ oligonucleotides bound to streptavidin coated paramagnetic beads with genomic DNA. We found that SNX-ligated DNA was efficiently enriched by shorter biotin-(GACA)₄ and (GATA)₄ oligonucleotides bound to streptavidin beads. Notably, 100 µl of magnetic beads were incubated with 1 µl (200 pmol) biotinylated oligo probes for 15 min at room temperature. The 5' biotinylated oligonucleotide primers were obtained from commercial sources (University of Calgary, AB, Canada). The bead:oligo complex was washed 3 times with 5× SSC using the MPC between washes, resuspended in 35 µl of 10× SSC, and held at 48°C for the hybridization steps. The target DNA was denatured by incubating 10 µl of SNX PCR product, 10 µl SNXf (competitor) (0.5 ng/µl) and 55 µl water at 95°C/15', then plunged into ice. The bead:oligo complex was combined with the denatured target (SNX PCR product+competitor) and incubated at 48°C for 60 min.

Some groups have reported successful enrichments at room temperature (RT) using magnetic beads (see Zane et al. 2002 and Fischer and Bachmann 1998). However, we did not obtain enrichment of GACA₄ or GATA₄ microsatellites in geoduck or eulachon (data not shown) at RT. All wash steps were performed without removing the sample from the 48°C environment. Using the MPC between washes, the three wash steps were performed as follows: 2×SSC+SNXf, 1×SSC+SNXf, 0.5×SSC+SNXf, using 200 µg

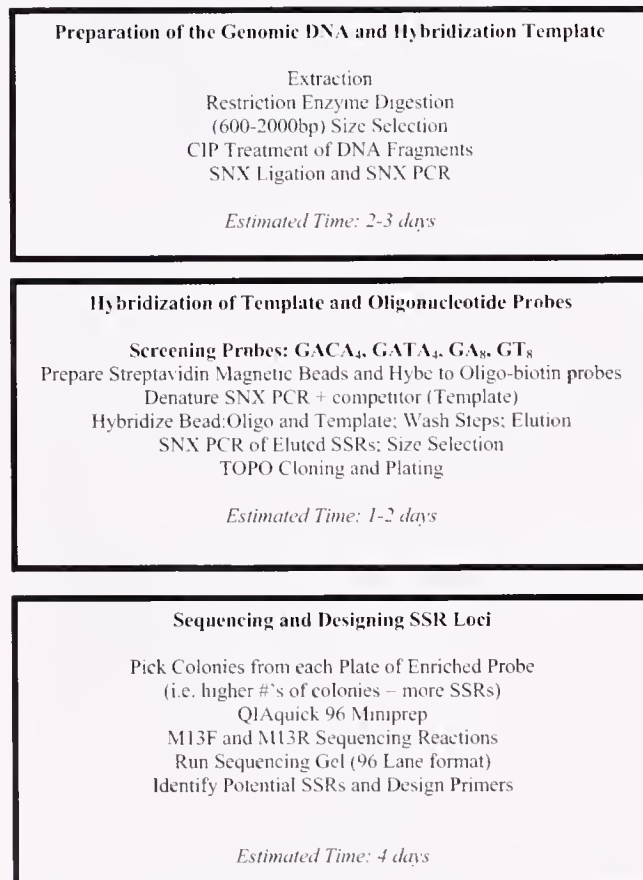

Figure 1. Flow chart of the magnetic bead enrichment protocol. Each major step is noted within the shaded boxes. The total elapsed time for the library experiment is approximately 7–9 days. The 96 well format greatly reduces the time and labour, thus offsetting the potential increase in consumable costs. In practice, one could produce successful library enrichment from a new species within two weeks.

SNXf per 1 ml of SSC. The presence of the SNX competitor in the hybridization and wash steps ensured a high level of stringency, thus reducing non-specific probe binding. The microsatellite-enriched fraction was eluted by adding 50 μ l of TE at 48°C to the bead:oligo:DNA incubated at 95°C for 15'. Using the MPC, the enriched fraction was removed without disturbing the streptavidin beads. The enriched fraction was used as the template in the SNX PCR, as noted above. By resolving the SNX PCR and oligo-PCR products on agarose gels, using each fraction (ligations, hybridisation, washes, elutions) as a template, the technical success was assessed (Table 1). Ideally, the smear of products amplified by the SNX primer declined with each wash step.

Following the SNX PCR with the enriched fraction as the template, the fragments were size selected (600–2000 bp), cloned and transformed using a TOPO Cloning 5' PCR kit (Invitrogen, Carlsbad, CA). The transformations were plated, grown overnight at 37°C and single colonies miniprep using a QIAprep 96 Turbo Miniprep Kits (Qiagen, Valencia, CA). Clones were sequenced using Big Dye Primer M13F and M13R Sequencing Kits (ABI, Foster City, CA). In general, the plates with the highest number of colonies correlated to the most abundant repeat motif. For the identification of unique or rare microsatellites, extensive probing from plates with fewer colonies was required.

Sequencing gels were electrophoresed on an ABI 377 automated sequencer using ABI Prism 377-96 Collection software (ABI). Sequences were viewed and base-called using Sequencing Analysis 3.4.1 (ABI). Sequencher software (Gene Codes Corporation, Ann Arbor, MI) was used to remove the vector, align and group sequences and highlight microsatellite repeats. PCR primers were designed for each potential microsatellite locus.

Over the past decade, we have isolated and applied microsatellite loci to population genetics studies of more than 20 marine fish and shellfish species. The substantial empirical data gained from these studies guides our ranking of microsatellite sequences for primer design in new species. Our criteria follows seven general rules (in order of sequence preference): Primers are designed to (1) All perfect tetranucleotide repeats of 10 to 35, (2) All perfect dinucleotide repeats of 15–45 (noting that those with over 25 repeats can contain substantial stutter), (3) Slightly imperfect tetranucleotide repeats of 13 or more, and (4) Compound di-di, tetra-tetra, and di-tetra repeats with little or no imperfections. Primers are generally not designed to (5) di/tri, tri/tetra or sequences containing stretches of more than five single nt, as these often result in 1-bp alleles, (6) Highly imperfect loci, as these often contain single base insertions or deletions, also resulting in 1-bp alleles, and (7) Tetranucleotide repeats containing three mononucleotides (e.g., AAAN). In general, if sufficient flanking sequence is available, three sense and three anti-sense primers are designed for each locus, which enables the detection of null alleles in the first round of screening and provides a variety of size ranges to choose from for the design of multiplexes. Because our population surveys generally contain sample sizes of 100 or more individuals, loci with high numbers of alleles are still considered potentially useful.

Polymerase chain reaction (PCR) amplifications were performed using 35 cycles of 94°C/30", 48–54°C/30", and 70°C/45". Each 8.0 μ L reaction contained 0.50 μ L of a 1:2 dilution of Chelex extracted DNA (approximately 0.01–0.03 μ g), 0.48 μ M of each primer, 0.80 μ M dNTP, 0.15 units of HotStarTagTM DNA polymerase (Qiagen, Valencia, CA) and 1 \times HotStarTagTM PCR Buffer containing Tris-HCl, KCl (NH₄)₂SO₄, 1.5 mM MgCl₂, pH 8.7. Primers were initially optimised by amplification of 8 individuals

size-fractionated on 10% non-denaturing polyacrylamide gels. Manual gels were stained with ethidium bromide, and sized against a 20-bp ladder using PhoretixTM 1D version 5.10 software (Non-linear Dynamics Ltd., Newcastle upon Tyne, UK). Multiple primers per microsatellite sequence were tested to aid in the identification of null alleles and to provide a range of product sizes for subsequent multiplexing. Null alleles and allele size ranges were assessed by amplifying 24 individuals for 2 to 3 primersets per polymorphic locus, size separated on manual gels. One sense primer for each polymorphic locus was then fluorescently labelled, and loci were incorporated into a multiplex for automated electrophoresis on an ABI 377 automated sequencer using 4.5% denaturing polyacrylamide gels. Allele sizes were determined with Genescan 3.1 and Genotyper 2.5 software (PE Biosystems, Foster City, CA), and the Genetic Data Analysis (GDA) program of Lewis and Zaykin (2001) was used to analyse allelic and genotypic frequency data.

RESULTS & DISCUSSION

The experimental time-table is outlined in Figure 1. The experimental design can be modified for high throughput, by employing a 96-well plate format MPC. This approach replaces the physically demanding, lengthy and potentially hazardous radioisotope method. The magnetic bead approach produced a high level of enrichment for tetranucleotide repeats in all three invertebrate species tested (Table 1). The microsatellite enrichment averaged 75% over all species/microsatellites surveyed. The level of enrichment of each microsatellite motif varied among species. In Dungeness crab, both GACA₄ and GATA₄ were highly enriched, at 85% and 82%, respectively. In geoduck clam, GACA enrichment was more successful (94% versus 45%) whereas in scallop, GATA was more highly enriched (92% versus 67%). Scallop was also highly enriched for CT₈, CCAT₄ and GACT₄ repeats.

Toth et al. (2000) demonstrated that di- and tetranucleotide motifs are the most common repeat in vertebrates. Epplen et al. (1998) compiled a table of representative microsatellite DNA sequences deposited in the EMBL/GENBANK data bank. They indicated that GAAA, AAAT, GATA and GGAA were the most common tetranucleotide repeats while GACA and GACT were rarer. Likewise, GT was the most common dinucleotide repeat followed by AT and GA. However, GATA and GACA were the most frequent tetranucleotide repeat in the bird, reptile and fish sequences surveyed (Toth et al. 2000). In human chromosomes, Katti et al. (2001) found tetranucleotide repeats were very frequent, with the most common type being (AAAN)_n. Indeed, Schable et al. (2002) obtained success in enriching for microsatellites from the dollar sunfish using (AAAG)₆ and (ACAG)₆. However, because AAAG repeats often contain imperfections such as AAG or AAAAG which result in 1-bp alleles, we did not enrich for (AAAN)_n microsatellites.

Herin, PCR protocols were optimised for tetranucleotide repeat containing microsatellites, which are generally found on the longer fragments. We note three steps in the enrichment process that were crucial to the obtainment of long fragments and sufficient flanking sequence. First, decreasing the SNX-ligation cycling steps from 18 to 5 cycles enhanced the length of flanking sequence. Second, increasing the number of cycles in the SNX-PCR from 30 to 40 enhanced the population of high molecular weight PCR fragments. Third, size selection of the 600–2000 bp fragments immediately following the restriction digest reduced self ligation of small frag-

TABLE 1.

Species used to test the enrichment protocol include geoduck (*Pab*), Dungeness crab (*Cma*), and Japanese scallop (*Pye*). All species were screened with GACA₄ and GATA₄ probes, with scallop probed for a variety of additional core repeats. The total number of clones sequenced, contained microsatellite repeats, and had primers designed are presented for each species. The % enrichment was determined by dividing the total number of microsatellite-containing clones by the total number of clones sequenced. Likewise, the % success was calculated by dividing the total number of useful loci by the total number of designed loci (primers for *Pye* have not yet been tested). Average insert length and average 3' and 5' flanking were calculated for each species.

Species	Probe Repeat	Number Sequenced	μsat Containing	Designed Loci	% Enrichment	% Success	Avg Insert Size (bp)	Avg 5' & 3' Flanking (bp)
<i>Pab</i>	GACA	33	31	10	93.94

ments and bias towards smaller products in the PCR. Fourth, a second round of size selection of the 600–2000 bp fragments after the SNX-PCR was imperative because of the small insert bias of TA cloning. Using these protocols, we obtained an average fragment length of 347 bp (scallop) to 450 bp (crab) and average 5' and 3' flanking sequences ranging in length from 89 bp (scallop) to 130 bp (crab) (Table 1).

To directly assess the effectiveness of the enrichment protocol described herein, we compared the resolution of tetranucleotide repeat loci in geoduck clams obtained under the enrichment protocol to traditional library screening. Using traditional techniques, we screened over 3×10^4 clones using ³²P-end labelled (GACA₉) and (GATA₉) oligonucleotides, as in Miller et al. (2001). Sixty-six putative microsatellite-containing colonies were sequenced, 30 of which were found to contain microsatellite repeats. Only a single clone contained a simple tetranucleotide repeat. The remainder of the clones contained dinucleotide repeats, although four clones contained compound di-/trinucleotide repeats. Hence, although libraries were probed exclusively with tetranucleotide repeats, most microsatellites obtained were dinucleotide repeat sequences. Alternately, using the enrichment protocol, we sequenced 55 clones, 41 of which contained microsatellite repeats. Of these, 22 clones contained simple tetranucleotide repeats, 8 clones contained simple dinucleotide repeats, and the remaining 11 clones contained compound di-/tetranucleotide repeats. Hence, 80% of the microsatellite sequences isolated under the enrichment protocol contained tetranucleotide repeats versus 16% using the traditional method.

Primers to thirteen microsatellite sequences isolated through magnetic bead enrichment of geoduck clam were designed and tested. In addition, primers to ten microsatellite sequences isolated through conventional radioactive library screening (described

above) were designed. In all, one tetranucleotide (*Pab* 117) and three di-nucleotide loci (*Pab* 101f, *Pab* 132 and *Pab* 156) isolated through conventional screening were chosen for use in population studies, and four tetranucleotide repeat loci (*Pab* 101e, *Pab* 105e, *Pab* 106e, and *Pab* 112e) from the enriched method were chosen (Table 2). Loci were chosen by of degree of polymorphism, clarity of alleles, and absence of (demonstrated) null alleles defined in the original small survey of 24 individuals.

Polymorphism of the eight geoduck loci was evaluated over approximately 200 individuals collected from two sites within British Columbia, Canada, one located in the Strait of Georgia and the other off the Queen Charlotte Islands. The geoduck microsatellite loci were highly polymorphic, with numbers of alleles ranging from 21 (*Pab* 156) to 60 (*Pab* 132) and expected heterozygosities ranging from 0.91 (*Pab* 112e) to 0.97 (*Pab* 156). However, significant deviations from Hardy-Weinberg (HWE) equilibrium caused by heterozygote deficits were found at all but three of the loci (*Pab* 101e, *Pab* 106e and *Pab* 112e). Heterozygote deficiencies were also observed at most loci isolated from geoduck clams in a previous study (Vadopalas and Bentzen 2001), and have been commonly observed in a variety of marine invertebrate species (e.g. Brown 1991; Miller et al. 2001; Pérez-Losado et al. 2002; Addison and Hart 2004). Possible explanations for heterozygote deficits in marine invertebrate species include the presence of null alleles, a temporal Wahlund effect gained through Sweepstakes style recruitment (Hedgcock 1994), inbreeding, non-random mating, and selection.

Primers to eighteen microsatellite sequences isolated from Dungeness crab were designed and tested. Nine of these loci were chosen for use in population studies. Two loci contained dinucleotide repeat units (*Cma* 107 and *Cma* 118), six loci contained

TABLE 2.

Nine polymorphic microsatellite loci were developed from Dungeness crab and eight for geoduck clam. Repeats denoted with (i) contain imperfect repeated motifs. Locus-specific annealing temperatures are shown under T_a (°C). Levels of polymorphism measured by number of alleles and expected (H_e) and observed (H_o) heterozygosity, and inbreeding coefficients (F_{is}) were calculated from a survey of approximately 200 individuals collected at two sites for each species. The asterisk (*) under H_o denotes loci that contain a deficit of heterozygotes and are significantly out of Hardy-Weinberg Equilibrium. Accession numbers for each locus are shown in the end column. The first four geoduck clam loci were obtained through traditional library screening methods in which ^{32}P -labelled GACA and GATA probes were utilised.

tetranucleotide repeats (*Cma* 102, *Cma* 103, *Cma* 108a, *Cma* 108b, *Cma* 114 and *Cma* 117), and one locus contained a compound di-tetranucleotide repeat (*Cma* 1). Polymorphism of the eight loci was evaluated over approximately 200 individuals collected from two sites within British Columbia, Canada: Hecate Strait and Port McNeil. The microsatellite loci isolated from Dungeness crab contained a moderate level of polymorphism. The number of alleles identified at each of the loci ranged from 6 (*Cma* 117) to 39 (*Cma* 107) with an average of 14.4 alleles per locus. Expected heterozygosity ranged from 0.57 (*Cma* 117) to 0.92 (*Cma* 107). Deviations from HWE equilibrium was observed for only one of the loci (*Cma* 107).

In summary, the magnetic bead enrichment protocol described herein was successfully employed to isolate tetranucleotide repeat loci from marine invertebrate species that have been notoriously difficult to work with using traditional isolation methods. The

enrichment protocol can be performed in a few as 7 days, where as, standard methods can take months. The high throughput format enabled us to screen, clone and sequence hundreds of microsatellites, thus facilitating rapid isolation of new loci for multiplex population analysis. To date, we have successfully utilised this protocol to isolate microsatellite loci from six marine invertebrate (herein) and fish species (Kaukinen et al., in press and unpublished data).

OVERVIEW, 24th MILFORD AQUACULTURE SEMINAR.¹ Walter J. Blogoslawski, US Department of Commerce, National Oceanic & Atmospheric Administration, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, 212 Rogers Ave., Milford, CT 06460

There were 164 registrants for the 24th Milford Aquaculture Seminar, a gathering of industry, research, and academic interests. By blending both the theoretical and practical aspects of aquaculture, the meeting permitted attendees an exchange of information concerning aquaculture methods outside their own expertise and provided a forum where the latest innovations were introduced and discussed.

Thirty-six formal papers and posters were presented by attendees from 11 US states, the District of Columbia, Brussels, Belgium, and Baja, Mexico. Meeting attendees represented 2 vocational aquaculture high schools, 10 universities, 4 marine laboratories, and several state and federal institutions involved in shellfish aquaculture. A highlight of the meeting was a set of papers reviewing the aquaculture research activities at the NMFS Milford Laboratory including immune response to toxic algal blooms, problems with growing large batches of microalgae, scallop culture, diseases that affect planted clams and oysters, and genetically enhanced farmed aquaculture products. Other papers covered state and federal impediments to siting aquaculture farms (NIMBY or Not In My Back Yard) and described how NOAA Sea Grant extension agents assist the aquaculture industry. Linda Chaves, NMFS Aquaculture Coordinator, detailed NOAA's position on aquaculture during a luncheon address.

A panel of scientists described the pitfalls and possibilities of introducing the Asian oyster, *Crassostrea ariakensis*, into Chesapeake Bay waters as a replacement for the native oyster, *Crassostrea virginica*, that has been devastated by disease. *C. ariakensis* has shown some potential as an alternative product for the ailing shellfish industry. Moreover, its introduction might help to restore ecologic function to diminished native populations. A careful methodical approach including the use of sterile triploid oysters is warranted.

At this year's seminar, representatives of 51 aquaculture companies gathered at an evening session for the annual meeting of the East Coast Shellfish Growers Association. The association's goals are to promote and protect shellfish members' needs in state and regional contexts and to involve all stakeholders in the task of enhancing the shellfish aquaculture industry.

The meeting was sponsored by the National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT. Abstract printing was courtesy of the US Department of Agriculture, Northeast Regional Aquaculture Center, N. Dartmouth, MA.

A NON-ELUCIDATED MORTALITY EVENT OF JUVENILE HARD CLAMS IN A HATCHERY SYSTEM. John Aldred,¹ Steven Pitchford,² and Bassem Allam³, ¹East Hampton Town Shellfish Hatchery, 159 Pantigo Road, East Hampton, NY 11937; ²USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; and ³Marine Sciences Research Center, Stony Brook University, Stony Brook, NY 11794

In the last few years, mortalities of juvenile bivalves sporadically occurred at the East Hampton Town Shellfish Hatchery (Fort Pond Bay, Montauk, NY), first in 1996 and again in 2001 and 2003. Histopathologic analysis performed on samples during the 2001 episode revealed heavy infestation by fungal mycelia in most tissues of dying animals. In the latest episode, batches of juvenile clams, generally about 1 mm in length, began to die off on May 19, 2003. An earlier batch of clams, which had been moved to a flowing water nursery system, seemed unaffected. Consistent with prior episodes, subsequent and apparently unaffected clam batches, if not moved to the nursery, would begin to die off in the hatchery juvenile systems usually as they approached 0.5 to 1 mm in length. Samples of juvenile clams, of different sizes and ages, some exhibiting symptoms and some not, were collected and submitted to standard histologic and staining techniques (hematoxylin eosin, Gram and GMS stains). Microbiologic analyses were performed on water samples taken from different parts of the system, but did not reveal any abnormal proliferation of heterotrophic bacteria. Histopathology analysis performed did not reveal any known pathogen in dying clams. The only consistent abnormal observation was the presence of chain-like microorganisms morphologically close to structures built by some colonial cyanobacteria, associated with some signs of starvation in affected juveniles. Whereas these structures were detected in four of five original samples (all 1 + mm in length), they were not detected in a fifth (0.3 mm) or subsequent sample (0.15 mm), both collected from conical tanks. The structures were found in larger clams after transfer to juvenile rearing tanks and seem to become more numerous with the progress of mortalities. Cyanobacteria of the genus *Planktothrix* and *Trichodesmium* have already been associated with bivalve mortalities, and microorganisms belonging to this group might be at the origin of juvenile mortalities. However, until the identity of the chain-like microorganisms is determined, the cause of the mortalities observed here remains unclear.

A FLOW-CYTOMETRIC METHOD FOR COUNTING MICROALGAL AND BACTERIAL CELLS IN THE SAME SAMPLE. Jennifer H. Alix and Gary H. Wikfors, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Numeric counts of microorganisms in aquatic samples often are essential to research and evaluation of aquaculture systems. Traditional methods of counting cells in the microscope or colonies on petri dishes are labor-intensive and subject to limitations in both

accuracy and precision. In water samples containing microalgae, bacteria, and other microorganisms, as well as non-living, suspended matter, proxy measurements, such as optical density, chlorophyll fluorescence, or packed-cell volume, are subject to error from interference of one particle type with another or inability to distinguish which types of particles are contributing to the measurement. Thus, particle enumeration often limits the temporal or spatial resolution of data. We have addressed this limitation with an admittedly sophisticated tool, the flow cytometer—not a tool expected to be available to most aquaculturists, but a versatile one if available!

The flow-cytometric (fcm) protocol we have been developing uses ratios of particles detected in the water sample with a known number of fluorescent, plastic microspheres added to the sample. Microalgal cells are differentiated from other particles by size and chlorophyll fluorescence measured in two detectors, and living particles have been differentiated from non-living by staining with several DNA-binding fluorochromes measured in a third detector. Identities of particles can be confirmed by physically sorting cells and observing them in the microscope.

Microalgal counts in both pure and open-tank (bacterized) cultures by our fcm method agree very well with microscope counts ($R^2 > 0.9999$) over three orders of magnitude (10^4 – 10^7), and bacterial counts from pure cultures agree reasonably well with plate counts. In open-tank microalgal cultures, clumping of bacteria in aggregates has made interpretation of counts difficult, but we are addressing this limitation with various anti-aggregating compounds with some success. Compared with plate counts, fcm counts of bacteria in microalgal tank cultures at least are in the same order of magnitude.

Processing time for each sample, including addition of reagents, fcm data acquisition, and data reduction, is approximately 3 minutes, which we estimate to be 1/3 the time for an algal microscope count alone. The labor saved is considerably greater if samples need to be settled and concentrated or diluted for valid hemocytometer microscope counts. The fcm method provides, in addition, some quantification of bacteria (subject to interpretation) and non-living particles with no further effort. We are applying this fcm, particle-counting method to studies of microbial and nutrient dynamics in open-tank, mass algal cultures.

THE STATUS OF QPX DISEASE IN NEW YORK. Bassem Allam,¹ Alistair Dove,² and Joshua Thiel³, ¹Marine Sciences Research Center, Stony Brook University, Stony Brook, NY 11794; ²Cornell University, Marine Sciences Research Center, Stony Brook University, Stony Brook, NY 11794; and ³New York State Department Of Environmental Conservation, Bureau Of Marine Resources, 205 N Belle Mead Road, East Setauket, NY 11733

The presence of the protistan parasite of hard clams quahog parasite unknown (QPX), was confirmed in different locations of Raritan Bay off the south shore of Staten Island during 2002.

Because of the importance of this clam population as a source for the hard clam relay fishery in New York State, we initiated a survey program to monitor the Raritan Bay population specifically as well as to assess the general distribution of QPX disease in hard clam populations from different locations of the marine district. Our results show that QPX is present among hard clams in Raritan Bay at relatively low prevalence in most surveyed sites (below 7%), but reaching higher levels in some cases (up to 30%). Seasonal changes in QPX incidence were noticed and a cyclical pattern of prevalence is suspected. There is some evidence that the prevalence of the infection is related to the density of wild clams in the field, with high QPX occurrence in areas with high clam densities. QPX was also detected at very low (background, <4%) levels in Oyster Bay and in the Peconic Estuary. Wild clams collected near transplant plots in the Peconic Estuary were negative with regard to QPX. To date, the only site displaying a high incidence of QPX (20%) in this estuary was found in Flanders Bay, a remote location from any transplant plot, suggesting that the presence of QPX in that site is unrelated to the transplant fishery. More data, however, are needed before drawing final conclusions. The QPX organism has been isolated from infected clams collected from Raritan Bay, and the molecular, physiologic, and ecological characterization of cultured parasites is in progress.

JUVENILE OYSTER DISEASE IN THE NORTHEAST: 2003 EPIZOOTICS RESULTED FROM INDEPENDENT ACQUISITIONS OF THE BACTERIAL AGENT. Katherine J. Boettcher and Aaron P. Maloy, Department of Biochemistry, Microbiology, and Molecular Biology, University of Maine, Orono, ME 04469

We have established the primary involvement of a *Roseobacter* species in juvenile oyster disease (JOD) in Maine, but prior to last year its potential role in other regions had not been verified. Further description of the bacterium is ongoing, but it has tentatively been named *Roseimarina crassostreae*. In 2003, samples of JOD-affected animals were obtained from locations in Maine, New York, and Massachusetts. The manifestation of the disease was similar at all locations (i.e. uneven valve margins and deposition of conchiolin), and the presence of these signs was correlated with extensive colonization by *R. crassostreae*. Previous characterization of isolates indicated that outbreaks of JOD result from a single infectious strain, and that once established the same strain can persist in JOD-enzootic systems year after year. These conclusions were supported by evidence obtained in 2003, which revealed that the Maine isolates were the same genotype as those isolated from the same location in the previous 3 years. Oysters from each epizootic in Massachusetts and New York were colonized by one of three strains of *R. crassostreae*. These could be differentiated from the Maine strains by differences in colony morphology and/or genetic markers. On the basis of these findings, we conclude that these outbreaks resulted from independent acquisitions of the bac-

terial agent at each of the affected locations. Continued development of management strategies should take into consideration that such potentially infectious environmental strains (rather than seed transfer) may be the most common source of new JOD epizootics.

COMMERCIAL CULTURE OF SOFTSHELL CLAMS HAS ARRIVED AND IS GROWING ON MASSACHUSETTS' NORTH SHORE. Joseph K. Buttner,¹ Mark Fregeau,¹ Scott Weston,¹ Bonnie McAneney,¹ Jack Grundstrom,² Anthony Murawski,³ and Evan Parker⁴. ¹Northeastern Massachusetts Aquaculture Center and Department of Biology, Salem State College, Salem, MA 01970; ²Ipswich Bay Cultured Clam Cooperative, 58 Railroad Ave. Rowley MA 01969; ³5 Upland Lane, Ipswich, MA 01938; and ⁴27 Turkey Rd., Ipswich, MA 01938

After a decade of restoration and enhancement efforts, two towns on Massachusetts' North Shore have initiated commercial culture of softshell clams, *Mya arenaria*. The Northeastern Massachusetts Aquaculture Center has supported these public and private initiatives with hatchery-reared clams.

Shellfishers in Ipswich and Rowley use similar techniques to capture wild spawn, seed sites and exclude predators. However, routes to commercialization differ. The Town of Ipswich supports a pilot study by two local, recent college graduates. In 2002, a 1.4 acre lease was approved for the bottom culture of softshell clams, the first such approval in nearly 40 years. Initially, wild caught seed were grown on prepared sites. Clams were captured and covered with 1/6" plastic webbing to exclude predators, predominantly the green crab (*Carcinus maenas*) and shorebirds. By summer 2003, many of the seeded clams had attained a legal size (>2 inches SL) and the first commercial harvest occurred. In excess of 40 bushels were harvested and marketed. In summer 2003, hatchery-reared seed clams ($n = 200,000$) as well as wild collected clams were stocked to enhance productivity of the leased flat. Town officials and culturists are assessing efficacy and refining protocols of the on-going pilot project.

The Town of Rowley initiated enhancement and restoration efforts on unproductive flats in the early 1990s, peaking with 800,000 hatchery-reared spat (12–17 mm) seeded annually in 2002 and 2003. The success of these culture efforts has generated enthusiastic support from town selectmen and the community at large. By fall 2003, the focus on public restoration evolved into a commercial endeavor. Four local clambers each obtained a 1-acre lease from the town for commercial production of softshell clams on tidal lands and then formed a cooperative. The appropriate permits to purchase and sell clams have been obtained. Permits for the harvest of cultured clams are pending, per modification by the Massachusetts Division of Marine Fisheries to coincide with established guidelines for wild clams from conditionally approved waters. The first harvest of marketable-size clams from leased flats is anticipated in summer 2005.

Over five acres of tidal flats are currently leased by North

Shore towns to community members for private aquaculture. Expansion to increase acreage, number of growers and to secure processing capabilities is being pursued. Success of the approach has not gone unnoticed as culturists from Kingston, MA; Oaks Bluff, MA; and Prince Edward Island, Canada have sought assistance to nurture public and/or private culture of softshell clams in their tidal waters.

GONAD MATURATION OF DELAWARE OYSTERS USING ARTIFICIAL FEEDS: AN EXPERIENCE WITHOUT CONTROLS. Walter J. Canzonier and Lisa M. Ragone Calvo, Maurice River Oyster Culture Foundation, Port Norris, NJ 08349

Controlled maturation of the gonad of Delaware Bay oysters outside the natural seasonal cycle has been problematic, and when this process has been pursued in the hatchery setting it has required the dosing of relatively small cohorts of potential spawners with massive quantities of cultured microalgae. In an effort to effectuate maturation out of season, a closed system was developed at the Haskin Shellfish Research Laboratory (NJ Agr. Expt. Sta., Rutgers University) in the winter of 1988, as part of a program to produce disease tolerant oyster seed on a commercial scale. A gonad maturation system (gonamaturator) was designed as a temperature controlled (22°C–24°C) side-loop of the main laboratory recirculated seawater supply. A shallow trough (4.8 × 0.9 m, operational pool depth 4 cm) was plumbed to permit continuous recirculation seawater at a rate of 34 L/min uniformly across its short axis via inlet and drain manifolds situated on the long axis. This configuration provided agitation to maintain the particles in suspension and afforded near uniform exposure of all the oysters in the trough. The water passed through an aeration/constant head column on each cycle through the loop and was continuously dosed (1 L/h) with a concentrated suspension of a specially formulated composite particulate feed via a diaphragm dosing pump and in-line mixing chamber prior to entering the inlet distribution manifold. The feed suspension consisted of a mixture of commercial corn starch, kaolin (extra fine grade) and a commercial microcapsule larval shrimp diet (Fripak Booster) at a daily rate of 19g, 11g, and 45g, respectively, per 50 to 65+ oysters. The suspension was prepared daily in cold freshwater, and the continuously stirred reservoir was maintained in a refrigerator at 4°C to minimize bacterial degradation. The side loop operation was continuously controlled by a programmer constructed of inexpensive and readily available electronic components. Hourly, the feed dosing pump was stopped for a 15 minute period to allow the oysters to exhaust the suspended feed; the trough and associated piping were then drained back to the main laboratory seawater system. The gonamaturator was then refilled to operating capacity, after which the circulation/feeding cycle was restarted. Activity of the oysters was monitored daily, and was judged to be optimal on the basis of pumping activity and fecal string production. Two lots of disease tolerant parent stock were conditioned to maturation in 38 and 18 days, respectively,

with minimal mortality during the maturation phase, and good spawning in a contracted commercial hatchery. Competence of the eyed larvae was judged satisfactory, as judged by eventual setting efficiencies in the range typically obtained in our remote setting operation. Previously, algal paste from two sources had been tried for conditioning, but with mixed results. Acceptance of this type of feed was poor to fair at best, as indicated by activity levels and feces production. Indeed, one batch of slurry from a commercial source completely inhibited opening and pumping by the majority of the oysters. Algal paste was eventually abandoned as a feasible alternative.

This project was partially funded by USEPA, Region III, Delaware Estuary Program Grant 66.456, a Delaware River & Bay Authority Industry Development Grant, and the New Jersey Sea Grant/Marine Science Consortium.

TRACKING LAB-BRED BAY SCALLOP GROWTH AND SURVIVAL IN THE NANTIC RIVER. Joseph Choromanski, Sheila Stiles, Dorothy Jeffress, Ronald Goldberg, and David J. Veilleux, USDOC, NOAA National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Selection efforts on the bay scallop, *Argopecten irradians irradians*, have provided laboratory-reared lines that allowed us to develop strategies for studying certain characteristics, such as growth and survival, in restoration projects. These strategies include increasing the frequency of phenotypic markers of striped shells for stock identification in enhancement and restoration efforts while maintaining or even increasing survival and growth rates. Over the course of two seasons, trials have been underway in the Niantic River in Connecticut with these stocks of scallops.

Scallops with and without striped shells were deployed in three tiered cages at two sites in the river. Cages were made of plastic-coated wire with a 7.5 cm mesh. Each cage measured 56 × 56 × 94 cm and was divided horizontally into three sections or tiers. Cage inserts of smaller mesh (10 and 17.5 mm) measuring 41 × 10 × 81 cm were used to hold the scallops. The initial year's experiment was deployed for growth and survival at densities of 100 scallops per tier with an equal number of striped and non-striped scallops from the same genetic lines. The cages were checked monthly to the end of the normal growing season to determine performance, with the added attention to shell deformities that might indicate density problems. Fouling organisms, which may prevent adequate water flow through the cages, were checked for and removed. Overwintering trials were then carried out to compare survival into the next growing season with the aim of utilizing the striped scallops as brood stock for restoration trials the following summer. Growth trials of a second line of striped scallops repeated these efforts during the second season. Preliminary data have shown favorable indications and will be compared with past studies at different sites and in lines maintained at the laboratory.

OBSERVATIONS ON PHENOTYPIC PLASTICITY AND BEHAVIOR IN A GENETIC LINE OF THE BAY SCALLOP, *ARGOPECTEN IRRADIANS IRRADIANS*. Allison Clark,¹ Sheila Stiles,² Dorothy Jeffress,² and Joseph Choromanski,² ¹University of Rhode Island, Kingston, RI 02881; ²USDOC, NOAA National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Organisms may change their physical characteristics or behavior to escape predators, a feature that can be known as phenotypic plasticity or inducible defense mechanism. A laboratory experiment was conducted using a genetic line of bay scallops, *Argopecten irradians irradians*, to test for phenotypic plasticity. Responses were measured because changes in morphometric traits and avoidance or attachment behavior caused by exposure to effluent from predators and damaged conspecifics. Six hundred juvenile scallops with and without striped shells from a mass-spawned genetic line were divided equally among 3 treated or exposed groups and 3 replicate controls in aquaria with flowing seawater. Six crabs, 3 each of green and mud crabs—predators of scallops in the wild—were placed in a cage inserted into a headjar and fed crushed scallops. These damaged conspecifics were from the same genetic line as the experimental scallops. A second headjar, similar to the treated experimental apparatus but without crabs, was used for the controls. The results of this experiment did not show significant difference between treated and control scallops for changes in total weight, shell weight, or shell length, following an effluent exposure period of 36 days. There also was no significant difference between scallops with and without striped shells in response to the effluent exposure or waterborne cues. It was observed, however, that the juvenile scallops were more likely to attach to the vertical sides of the tank when exposed to the effluent. This result highlights the importance of a vertical substrate, such as eelgrass, to the survival of young bay scallops.

A REVIEW OF LEGAL AND POLICY CONSTRAINTS TO AQUACULTURE IN THE US NORTHEAST. John A. Duff,¹ Tessa S. Getchis,² and Porter Hoagland³, ¹Environmental, Coastal and Ocean Sciences Department, University Of Massachusetts, Boston, MA 02125; ²Connecticut Sea Grant, 1080 Shennecossett Road, Groton, CT 06340; ³Marine Policy Center, Woods Hole Oceanographic Institution, Woods Hole, MA 02543.

Throughout the United States, aquaculture firms face a wide variety of laws and regulations that govern the manner in which they plan, site, and operate aquaculture facilities. It is obvious that aquaculture cannot be conducted in the absence of a legal system that clarifies or establishes property interests, provides a means for the protection of these interests, and ensures the safety of the product for consumers.

Although a legal framework is necessary for aquaculture to exist as an industry, there are many instances where uninformed, outdated, or inappropriate regulatory regimes impede aquaculture

development. Inconsistencies in the law can lead to an uncertain legal environment for aquaculturists. Regulators often are put in the conflicting position of promoting the development of the industry and regulating its effect on other uses of the land and sea. Firms are sometimes forced to undertake activities while lacking adequate information or a complete understanding of laws and regulations. Conflicts and concerns may be left unresolved until an issue is brought before an adjudicatory body. Legal constraints such as these detract from the stability and certainty that otherwise would facilitate sustainable aquaculture development, slowing or halting the growth of the industry, or perhaps even leading to its decline.

During the summer of 2003, we reviewed a range of aquaculture policies in an effort to identify those laws and regulations that may impede development unnecessarily within the northeastern United States. Through an informal survey of industry and government officials and a review of the literature, we find that specific laws and policies or the absence of laws and policies can be argued to impose constraints on growth in certain segments of the industry.

The northeastern "aquaculture industry" comprises a set of markets that may or may not be closely linked or even share technologic approaches. Typically, we conceptualize the structure of a market as a "vertical" flow of product from hatchery to grow-out to the downstream activities of processing, distribution, and final retail sale to the consumer. Firms may or may not be vertically integrated from production through retail. A number of separate markets exist for individual species of fish or shellfish. Some of these markets may be closely related; for example, blue mussels and hard clams are economic substitutes. Others may be very distinct, as baitfish are not close substitutes for farm-raised trout. Another cross-cutting issue concerns production technologies, which might be similar across markets but could differ within the same market.

Market and technologic factors could influence the extent to which a particular law or policy is perceived as a constraint. As a hypothetical example, a firm that processes cultured shellfish might like to see more farm production, which would reduce the price that it pays for raw product. Thus, this firm, situated downstream in the processing sector of the industry, might argue that riparian interests limiting the number of tideland leases are a clear constraint to industry development. On the other hand, firms with existing leaseholds might prefer that it be difficult for competitors to obtain access to additional areas because more production could reduce their own revenues. The extent to which these considerations are valid depends upon competition in the market (i.e., are producers price-takers who are selling their product at marginal cost?). These are the kinds of issues that should be kept in mind when thinking about the extent to which laws and regulations are truly constraints in a broadly defined US northeastern aquaculture industry.

We have identified 11 policy and legal issues that likely con-

strain the growth of the industry. In rough order of importance, these issues include: administrative and jurisdictional overlaps, lease and tenure processes, control of disease, interstate transport of product, competition with foreign imports and international trade barriers, policies governing interactions with protected species or impacts on habitats, rules concerning the culture of commercially harvested species, federal and state effluent regulations, culturing of genetically modified organisms, culturing non-indigenous species, and permitting in the US exclusive economic zone.

The most important potentially constraining issue concerns administrative complexity (often referred to as administrative "overlap"), where confusion about the relevant rules may lead to excessive financial and time costs. It is important to recognize that criticisms of administrative overlaps sometimes are inapt in that there may be no explicit "overlap" in the strict sense of two agencies regulating the same activity. In discussions with both industry participants and government officials, we have found that the term "overlap" often is used in a general sense to connote the complexity of regulation and the confusion that is the predictable consequence of that complexity.

A review of state statutes governing the designation of aquaculture "lead agencies" suggests that northeast states have made substantial efforts in recent years to respond to concerns about jurisdictional overlap. The recurring identification of administrative overlap as an industry impediment may be one of perception as much as effect. Nonetheless perceptions may have real impacts and, as such, states might consider efforts that would characterize aquaculture-related laws and regulations as residing in one "place."

Issues relating to interstate trade are perceived by many in the industry to be among the most constraining. In the future, research might usefully be directed at characterizing the laws and policies among the states of the northeast region that relate to animal health, including disease inspections and certifications. Also, state laws and regulations that restrain trade on the basis of conserving and managing wild harvest fisheries ought to be made clearer. Increasing the transparency of these rules and highlighting non-uniformities among disparate state approaches to the control of movements of diseases and invasive species, as well as to conservation of fishery resources, is likely to lead ultimately to a more homogeneous and less confusing regional legal regimen.

We also heard interest voiced by the industry in the development of so-called best management practices (BMPs). There are a number of precedents in other regions or internationally, such as the aquaculture industry in Europe, where BMPs have been adopted and implemented by participants in specific markets. A perceived advantage of the BMP approach is that it emerges as the product of consensus among industry participants, sometimes guided by government agencies. As such, BMPs are a form of soft law, a set of normative principles that does not involve explicit regulation. It would be productive to direct legal and policy re-

search toward understanding the implications of BMPs for market structure, their effectiveness in achieving stated objectives, their costs in comparison with government regulation, and their resiliency over time.

A REPORT ON THE 2003 CONNECTICUT SHELLFISH INDUSTRY SUMMIT. Tessa S. Getchis, Connecticut Sea Grant, 1080 Shennecossett Road, Groton, CT 06340

In November of 2003, individuals representing 30 commercial aquaculture businesses, several industry groups and associations, and members of Connecticut Sea Grant Extension, met to discuss the status of Connecticut's shellfish industry. The goal of the meeting was to identify the key challenges facing the State's industry, and to propose methods for addressing the challenges through collaborative research and cooperation with other stakeholders. The objectives of the meeting were: (1) to develop a list of challenges and needs (rationale for solving industry problems, grant development, etc.); (2) to prioritize challenges and needs (high, medium, or low priority); and (3) to draft a report of the discussion and conclusions. The report was drafted to solicit input and assistance from industry associations, councils, university researchers, educators, legislators, regulators, etc.

The participants of the summit ranked challenges to the shellfish industry in order of importance. Among the challenges ranked high were: (1) permitting restrictions on submerged and/or floating shellfish cultivation gear; (2) a confusing regulatory environment; (3) interaction with competing user groups in Long Island Sound; (3) increase in non-water based uses of the coastal zone resulting in lack of adequate workspace for industry; (4) state natural oyster beds have not been revitalized in several years; and (5) perceived negative impact on the industry resulting from the merger of the State Departments of Agriculture and Consumer Protection. Those challenges, which ranked medium to high, were: (1) interaction between eelgrass and shellfish cultivation gear; (2) oyster disease; (3) increased competition in shellfish markets, depressed prices for product; and (4) negative public perception of aquaculture in the state. Of medium importance were: (1) lack of industry leadership and (2) intrusion of energy line crossings in Long Island Sound. Of low to medium importance was limited amount of applied aquaculture research at Connecticut universities. Challenges ranked low by the participants included: (1) impact of invasive and native fouling organisms on gear, leading to increased maintenance costs; (2) inconsistent regulations for interstate transport of seed and product; and (3) increased fishing pressure on hard clams.

ENVIRONMENTAL CONDITIONS AND EXPERIMENTAL INFECTIONS WITH *P. MARINUS* MODULATE CELLULAR DEFENSE MECHANISMS IN THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*. Michael Goedken and Sylvain De Guise, Department of Pathobiology and Veterinary Science, University of Connecticut, 61 North Eagleville Road, U-89, Storrs, CT 06269

The fast growing oyster aquaculture industry is greatly hindered by *Perkinsus marinus* and *Haplosporidium nelsoni*, which can kill up to 80% of production. The relationship between parasites, oyster defense mechanisms and their environment is unclear. Phagocytosis (using fluorescent beads) and apoptosis (using Annexin-V FITC) of eastern oyster (*Crassostrea virginica*) hemocyte subpopulations were quantified at the single cell level utilizing flow cytometry. The influence of salinity (428 mOsm or 1.006 vs. 1006 mOsm or 1.025) and temperature (11°C vs. 25°C) were evaluated experimentally. Forward and side scatter distinguished two populations of hemocytes (granulocytes and hyalinocytes) with previously demonstrated unique functional characteristics. Controlled environment and infection studies revealed significant immune function alterations. Phagocytosis in granulocytes, but not in hyalinocytes, was higher at low salinity (428 mOsm or salinity of approximately 1.009) than at high salinity (1006 mOsm or salinity of approximately 1.025) when the water temperature was 25°C. Phagocytosis was not affected by salinity when the water temperature was 11°C. Temperature had no effect on hemocyte phagocytosis at either salinity. Apoptosis in both granulocytes and hyalinocytes was higher at 11°C than at 25°C when the water salinity was low (428 mOsm). Temperature had no effect on hemocyte apoptosis when salinity was high (1006 mOsm). Salinity had no effect on hemocyte apoptosis at either water temperature. Apoptosis in both granulocytes and hyalinocytes was higher upon *in vitro* infection with *P. marinus* compared with uninfected control cells. We demonstrated experimentally that water salinity, water temperature, and experimental infection with *P. marinus* modulated oyster defense mechanisms. A better understanding of how these variables affect oyster defense mechanisms may lead to management strategies that will result in reduced disease morbidity and mortality for oyster producers.

MONITORING SUCCESS OF BAY SCALLOP RESEEDING AS PART OF THE NORTH CAPE OIL SPILL SHELLFISH RESTORATION PROGRAM. Heidi J. Green,¹ Karin A. Tammi,² and Michael A. Rice³, ¹Department of Marine Affairs, University of Rhode Island, Kingston, RI 02881; ²Ridem Division Of Fish and Wildlife Coastal Fisheries Laboratory, Wakefield, RI 02879; ³Dept. of Fisheries Animal and Veterinary Science, University of Rhode Island, Kingston, RI 02881

On January 19, 1996, during a storm, the *North Cape* barge and the tugboat *Scandia* grounded off the coast of Moonstone Beach in South Kingstown, Rhode Island. The barge spilled approximately

828,000 gallons of No. 2 home heating oil into Block Island Sound and surrounding tidal waters. Large numbers of crustaceans, mollusks, birds, amphipods, and fish were killed due to the oil spill. A legal settlement resulted, requiring the responsible parties to compensate for restoration, including \$1.5 million allocated to shellfish restoration using bay scallops, *Argopecten irradians irradians* (Draft Shellfish Restoration Plan and Supplemental Environmental Assessment for the North Cape Oil Spill [DSRP], 1999). In September 2002, the Trustees (Rhode Island Department of Environmental Management (RIDEM), National Oceanic and Atmospheric Administration [NOAA], and the US Department of the Interior [DOI]) initiated a bay scallop restoration program by re-seeding Point Judith Salt Pond. An estimated 679,640 of 25-mm multicolored bay scallops were seeded near major eelgrass beds at a density of 0.84 scallops/m². Seeding encompassed an estimated 805,000 m² and was restricted to scallop habitat in the midsection of the pond. In the summer 2003, a study was conducted to evaluate the re-seeding effort by using artificial spat collectors. A total of forty longlines and 800 spat collectors were deployed over four study sites in the pond. Scallop recruitment to the collectors was very poor ranging from only 0.01 to 0.158 scallops/collector; indicating that the Fall 2002 scallop seed did not survive to “throw a spawn” in the summer of 2003.

IMPROVING THE EASTERN OYSTER BY INTERSTRAIN HYBRIDIZATION. Ximing Guo,¹ Susan Ford,¹ Gregory DeBrosse,¹ and Roxanna M. Smolowitz,² ¹Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349; ²Marine Biological Laboratory, 7 MBL Street, Woods Hole, MA 02543.

The eastern oyster industry in the Northeastern region faces three major diseases: MSX (caused by the parasite *Haplosporidium nelsoni*), Dermo (caused by the parasite *Perkinsus marinus*), and the juvenile oyster disease (JOD, probably caused by a bacterium). Rutgers University has been breeding oysters for disease-resistance since the early 1960s and produced strains showing strong resistance to MSX and some resistance to Dermo. Breeding at the F.M. Flower Oyster Company has produced a strain (FMF) showing superior growth and JOD-resistance. As part of a project funded by NOAA's Oyster Disease Research Program, we produced and evaluated the Rutgers NEH strain, the FMF strain and their hybrids (HYB) along with a global susceptible control (ME) and local controls that were normally cultured at each of the four deployment sites in NJ (2), CT, and MA. Oysters were produced in June 2000, deployed in July 2000, and evaluated for 27 months. Dermo exposure was heavy at most sites, whereas MSX and JOD infections were low or absent. At Cape Shore (NJ) where infection was the heaviest, NEH and HYB had the lowest cumulative mortality, 43.5% and 43.6% respectively, compared with 82.3% for FMF, 99.4% for ME, and 81.1% for the local control (Delaware Bay wild). Mortality patterns were in general agreement with

Dermo infection levels observed. In growth, HYB was the same as FMF and faster than NEH, whereas ME and the local controls grew the slowest. The hybrid offered the highest yield by surviving as well as the NEH strain and growing as fast as the FMF strain. Despite some variations, data from other sites showed the same pattern in growth and survival.

IMMUNE RESPONSES OF TWO POPULATIONS OF THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*, TO NATURAL AND SIMULATED BLOOMS OF THE DINOFLAGELLATE, *PROROCENTRUM MINIMUM*. Hélène Hégaret and Gary H. Wikfors, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Recurring summer blooms of the dinoflagellate, *Prorocentrum minimum*, have been observed for decades in Lagoon Pond, Martha's Vineyard, MA. These blooms seem to interfere with shellfish aquaculture production, both in the Martha's Vineyard Shellfish Group (MVSG) hatchery and in the pond. In cages suspended from the MVSG dock in Lagoon Pond, we placed juvenile oysters, *Crassostrea virginica*, from 2 sources: (1) progeny of broodstock maintained in Lagoon Pond for many generations (“native”) and (2) seed from a Maine hatchery where *Prorocentrum* blooms have not been observed (“non-native”). Oysters were analyzed for cellular immune-system profiles using flow-cytometric analyses for hematologic characteristics and several hemocyte functions. Hemocyte measurements were made after several weeks of acclimation and during two *P. minimum* “bloom events”—one simulated by the addition of cultured *P. minimum* to natural plankton in basins with flowing seawater, and the other naturally occurring.

For both populations of oysters, *P. minimum* exposure had a significant effect upon immune profile. Moreover, natural and artificial blooms of *P. minimum* triggered a similar immune response in the oysters, indicating that the artificial bloom was a good simulation of a natural bloom. “Native” and “non-native” oysters differed significantly in one key immune-function parameter—hemocyte oxidative burst. This difference between the two oyster populations suggests that the native oyster population may have been selected genetically for a more effective defense response to *P. minimum*, because invertebrates do not have an adaptive immune system by which an individual can improve its response following initial exposure to a pathogenic or toxic organism. These findings also offer clues to possibly explain differential survival of “wild” and cultured bivalves in waters experiencing harmful algal blooms.

SARGENT'S COVE, A CONNECTICUT SHELLFISH HATCHERY. Laura Ibars, Erin McManns and Javier Saenz De Pipaon, Sargent's Cove of Connecticut LLC, 132 Water Street, South Norwalk, CT 06854

Sargent's Cove of Connecticut is a new shellfish hatchery located in South Norwalk, Connecticut and a nursery in Darien,

Connecticut. The company is focused on the American oyster, *Crassostrea virginica*, and the hard clam, *Mercenaria mercenaria*, with a production goal for 2004 of 50–100 million oysters.

Five types of algae are grown at the hatchery for broodstock, larvae, and post set oysters: Brown algae (CCMP609 and T-Iso); green algae (PLY429); and diatoms (3H and Chaet).

The broodstock oysters are collected from different farmed oyster beds of Hillard Bloom Shellfish and are conditioned for approximately 6 weeks. The larvae are drained every 2 days until ready to set and then are moved to setting silos (using a downweller system) with clamshell cultch.

The land-based nursery has 12 tanks used as an upweller system where fresh water from Long Island Sound is constantly pumped, although no algae are added to the juvenile oysters then. The only work at this point is sorting and cleaning. Once the juveniles are larger than 1 mm they are moved to the FLUPSY, powered by electricity and tides. Here they will stay until they attain at least 25 mm in size. Once they are big enough they are planted on Hillard Bloom Shellfish farming grounds for 1 or 2 years after which commercial size is attained and the product is ready for market (at least 75 mm in size).

RE-CLAM-ATION OF UNDERWATER LANDS: THE NATURE CONSERVANCY'S EFFORTS TO RESTORE THE GREAT SOUTH BAY, NEW YORK. Carl Lobue, The Nature Conservancy Long Island Chapter, 250 Lawrence Hill Road, Cold Spring Harbor, NY 11724

In December 2002, in the largest transaction of its kind, the parent corporation of the Bluepoints Company transferred 11,500 acres of submerged land in New York's Great South Bay to The Nature Conservancy (TNC). This underwater land holding, which covers about 20% of the underwater lands in Great South Bay, provides an unprecedented opportunity to explore the effectiveness of a variety of alternative strategies for restoring key ecologic targets such as hard clam populations and seagrass communities. The Conservancy has formed a coalition of resource managers, scientists, and stakeholders called the Bluepoints Bottomlands Council to help formalize a long term management plan for these underwater lands and to assist with the development and implementation of system-wide restoration initiatives. Hard clams are the group's first ecologic target.

Hard clams are a keystone species in the bay. As nature's water filters, healthy stocks of suspension feeding bivalves, particularly long-lived species such as clams and oysters, are ecosystem engineers that are critical for maintaining a stable plankton community. After the loss of native oyster stocks in the last century, hard clams became the dominant suspension-feeding bivalve in the system, filtering 40% of the bay daily. Hard clams were also a principal component of the benthic community, creating structure and transporting pelagic production to the benthos.

Hard clam populations in Great South Bay have undergone an

extraordinary decline over the past 30 years reducing annual harvest rates by over 98% from their peak in the mid 1970s. It is widely acknowledged that the initial stock declines were a result of unsustainable harvest; however, in recent years the relative exploitation rates have declined whereas recruitment has continued to remain poor. This poor recruitment seems to be a result of low and sparsely dispersed spawning stock combined with poor overall food quality. Despite the aquaculture activities by the Bluepoints Company, the property it formerly owned had fallen to the same fate as the adjacent public lands. The hydraulic escalator dredges it used to harvest clams resulted in a clam population that is an order of magnitude lower than that on the depleted public lands (averaging 0.18 legal-sized clams per square meter in formerly productive areas). The current population of hard clams in the bay is estimated to filter about 1% of the bay daily and clams have not been replaced by other suspension feeders.

The Conservancy recently received support from the NOAA CRP to establish a network of spawner sanctuaries on TNC underwater land in Great South Bay. This effort will also monitor all the life stages in these areas from the survivability and spawning of stocked clams, into the planktonic stages through recruitment. Future plans include working with the towns, county, state, and federal agencies to consolidate existing information, coordinate bay-wide surveys, develop and implement a bay-wide spawner sanctuary plan, and protect new clam sets that occur on TNC property. In the long term the Conservancy hopes to foster system-wide shellfish management strategies that will promote sustainable harvest rates and support adequate shellfish abundance to maintain a healthy ecosystem function.

ASSESSING SHELLFISH AQUACULTURE ALONG THE EAST COAST. Sandra Macfarlane¹ and Gef Flimlin², ¹Coastal Resource Specialists, PO Box 1164, Orleans, MA; ²Rutgers Cooperative Extension, 1623 Whitesville Road, Toms River, NJ 08755.

The East Coast Shellfish Growers Association determined that developing best management practices for East Coast shellfish aquaculture was a high priority. As a prelude to that effort, an important step was to gain an understanding of the extent of the industry. The authors surveyed the Atlantic coastal states to investigate the number and size of leases, total acreage under lease agreements, species cultured, methods used, number of people unemployed, regulatory framework, user conflicts, and local issues. Results confirmed anecdotal evidence that the industry along the East Coast is comprised of many individuals farming relatively small leases (5–10 acres). Nearly 3,000 leases are currently in use for over 50,000 acres (excluding VA that has 100,000 acres leased but few acres currently under cultivation). Oysters and hard clams are the principal species, regulatory frameworks have many commonalities. The next challenge will be to find commonalities among this diverse industry to develop a meaningful code of prac-

tice and some sort of management system that will encourage the industry to thrive and grow but will also protect the public waters in which the leases are held in the public trust.

HOW INVERTEBRATE ABUNDANCES CORRELATE WITH QUAHOG ABUNDANCES IN FOUR BAYS IN THE NORTHEASTERN UNITED STATES. Clyde L. Mackenzie, Jr., USDOC NOAA Northeast Fisheries Science Center, James J. Howard Marine Sciences Laboratory, 74 Magruder Road, Highlands, NJ 07732

The abundance of quahogs, *Mercenaria mercenaria*, differs widely in four bays in the northeastern United States. Point Judith Pond in Rhode Island and Raritan Bay in New York–New Jersey have abundant quantities of quahogs, but Great South Bay in New York and Barnegat Bay in New Jersey now have relatively sparse quantities. Further, the meats of quahogs in Great South Bay and Barnegat Bay commonly are gray rather than the preferred creamy-white, and in Great South Bay quahogs grow slowly and their meats are thin. Great South Bay and Barnegat Bay once had large abundances of quahogs and were large quahog producers. Fishermen harvest quahogs in the four bays using mostly bull rakes, but also tongs. Harvesting pressure on the quahogs is relatively heavy in Point Judith Pond and Raritan Bay, but due to low abundances, harvesting is light in Great South Bay and Barnegat Bay.

This study was conducted to determine whether data on the abundances of the benthic invertebrates associated with the quahogs in the four bays would aid in determining the causes of the quahog declines in Great South Bay and Barnegat Bay. If the other invertebrates were also relatively scarce in the two bays, then it was presumed to be unlikely that overharvesting was the primary cause of the declines in quahog abundances. In 2003, the invertebrates in the four bays were sampled with a 6×6 cm hand grab. All four bays had a broad array of invertebrate groups: mollusks, crustaceans, polychaetes, and nemerteans. Nearly all were juveniles. Point Judith Pond and Raritan Bay had an average of about 1,200 invertebrates/m², whereas Great South Bay and Barnegat Bay had significantly fewer: 186 invertebrates/m² and 365 invertebrates/m², respectively. It is concluded that over-harvesting did not lead to the quahog declines in Great South Bay and Barnegat Bay, but rather they probably were mostly due to the effects of brown tides (caused primarily by *Aureococcus anophagefferens*) and perhaps other detrimental components in the water and to predation by blue crabs, *Callinectes sapidus*. Other factors besides brown tides may contribute to poor water quality in the bays, because resident times of water in Great South Bay and Barnegat Bay can be at least 2 months. Brown tides and blue crabs have become abundant in the two bays during the past 20 years, but neither are abundant in Point Judith Pond and Raritan Bay. In Great South Bay and Barnegat Bay, poor water quality, in part due to the brown tides, most likely prevents normal gamete production, larval development, and growth of the bays' invertebrates. Also,

after their larvae settle blue crabs eat most of the invertebrates, including quahog seed.

THE SLOW DEVELOPMENT OF CULTURE (AQUACULTURE) OF SHELLFISH AND FINFISH IN ESTUARIES OF EASTERN NORTH AMERICA AND ITS FUTURE. Clyde L. Mackenzie Jr., USDOC, NOAA Northeast Fisheries Science Center, James J. Howard Marine Sciences Laboratory, 74 Magruder Road, Highlands, NJ 07732

The commercial culture of bivalve shellfish and finfish has proceeded slowly and is not likely to expand much in the eastern estuaries of Canada, the United States, and Mexico. The principal reason for this is that estuarine shorelines and waters have been increasingly taken over by residential and industrial development, piers and boats. The culture described is the rearing of young stages in privately-owned hatcheries followed by growout of the young to market size in leased estuarine plots (aquaculture). Other than *Mercenaria mercenaria*, of which an estimated 20% of total United States production is from hatchery-growout culture (Milford hatchery-VIMS grow-out methods), this type of production of *Crassostrea virginica*, *Mya arenaria*, and *Argopecten irradians* is minute when compared with that of wild set. In Canada, shellfish aquaculture is practiced on a limited scale whereas salmon production has reached significant levels.

The reasons for the low production of such-cultured shellfish are (1) space to operate hatcheries has been limited by high costs of shorefront land; (2) growout on beds is also limited because non-hatchery shellfish are present in most otherwise suitable areas and thus they are unavailable for leasing; (3) environmental regulations are strict; (4) some otherwise available sites are polluted; (5) home, industrial and marina owners, and recreational boaters whose numbers are increasing rapidly, have found shellfishing operations (stakes and floats and men working in leased areas) objectionable; (6) large natural sets of shellfish on public and leased beds occur frequently and after they grow they are highly competitive in markets; and (7) consumer demand for shellfish is limited.

The culture of finfish, whose market demand is strong, has been nonexistent except for salmon in Canada and Maine. There are a number of reasons for this. Some are biologic/ecologic such as unfavorable extremes of temperature that limit the growth and survival of many potential aquaculture species. Others are logistical such as severe storms that threaten costly nets and cages. Still others impact the economics of enterprises such as the high cost of fish feed and other basic materials, to say nothing of high labor costs in these regions. Moreover, consumers are increasingly wary of farm-raised meat products owing to the perception of unacceptable use of additives required in their production. This applies to aquaculture products as it does to more conventional farmed products. And lastly, shorefront homeowners don't want buoys or cages that spoil their view of the waterway.

Perhaps a few shellfish and finfish species can be found that could be cultured in the estuaries in tiny selected areas for "niche" gourmet and ethnic markets. The shellfish species might be *A. irradians*, high quality *C. virginica*, heat tolerant *M. arenaria*, and cockles (*Anadara* sp.) and others. Such species need to be selected, growout areas found, and after-markets identified. Then hatchery-growout culture can be successful.

OYSTER PRODUCTION AT FISHERS ISLAND OYSTER FARM. Steve Malinowski, Fishers Island Oyster Farm, Fishers Island, NY 06390

Fishers Island Oyster Farm has been in operation for 22 years; first as a hard clam (*Mercenaria mercenaria*) producer and for the last 16 years as a producer of American oysters (*Crassostrea virginica*). During 2003, 650,000 oysters were produced exclusively for the half shell trade. Additionally, sales of seed oysters and hard clams account for approximately one third of total revenues.

Oyster and clam seed is produced in a 22' × 28' hatchery and transferred first to land based upwellers at 1 mm and then to FLUPSYs at 3–4 mm. After attaining 12 mm, oysters are stocked into pearl nets and grown for the remainder of the first season in a salt pond. The following spring, approximately 20% to 30% of the oysters are stocked into 5 tier lantern nets and suspended from long lines of buoys in West Harbor, Fishers Island Sound (5-acre New York State Temporary Land Use Assignment). The remainder of the seed is sold to other growers.

Due to fouling organisms and the habit of oysters growing into one another and the mesh of the nets, a considerable amount of handling is required. All work is accomplished with two motorized rafts (8' × 16') in the salt pond and two skiffs (21') in West Harbor. By the end of the second growing season (18 mo from spawning) approximately 50% to 75% of oysters are marketable.

SURVIVORSHIP OF WIND-DRIVEN BEACHED BAY SCALLOPS, *ARGOPECTEN IRRADIANS IRRADIANS*, AFTER RETURN TO NANTUCKET HARBOR. Andrew W. McCandless,^{1,2} Peter B. Boyce,³ Robert S. Kennedy,³ W. Forrest Kennedy,⁴ Valerie A. Hall,⁵ and Frank A. Dutra^{6,7}, ¹Maria Mitchell Association, 4 Vestal Street, Nantucket, MA 02554; ²Nantucket High School, 10 Surfside Road, Nantucket, MA 02554; ³Maria Mitchell Association, 4 Vestal Street, Nantucket, MA 02554; ⁴Department Of Ecology and Evolutionary Biology, Cornell University, Ithaca, NY 14853; ⁵Nantucket High School, 10 Surfside Road, Nantucket, MA 02554; ⁶Maria Mitchell Association, 4 Vestal Street, Nantucket, MA 02554; and ⁷Nantucket Shellfish Association, 147 Orange Street, Nantucket, MA 02554

On November 14 and 15, 2003 during high northwest winds and wind-driven higher tides than usual, large numbers of bay scallops, *Argopecten irradians irradians*, washed ashore at Wauwinet and Pocomo beaches in Nantucket Harbor. On November 15

and 16, scallopers and volunteers rescued hundreds of thousands of scallops from the shore, and deposited them back into the harbor. To determine the survivorship of the rescued scallops and thus the value of the scallop rescue effort, we placed 351 scallops in four modified wire lobster traps in 2 m of water (MLW) west of Pocomo Head in Nantucket Harbor on November 16. Group 1 contained 80 seed scallops exposed for 3 hours or less on the Pocomo shoreline; Group 2 and 3 contained 70 large seed and/or "nub" scallops each, recovered from the eelgrass wrack in Wauwinet that had been there for 12 hours or less; and Group 4 contained 131 seed exposed in the Wauwinet wrack from 24 to 36 hours. After 42 days on December 28, we found 340 live, and only 11 dead scallops in the pens: 1 dead in Group 1, 2 in Group 2, 6 in Group 3, and 2 in Group 4. This represents a 96.9% survival rate of the rescued scallops.

HOW HIGH PH'S CAN AFFECT THE CHEMISTRY IN LARGE VOLUME CULTURES OF *TETRASELMIS CHUI* (PLY429). Shannon L. Meseck and Barry Smith, USDOC, NOAA National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

For microalgal photosynthesis to occur, free dissolved carbon dioxide or carbon dioxide in the form of carbonate ion, needs to be present. In natural aquatic ecosystems, dissolved carbon dioxide generally is high enough to not limit phytoplankton growth. In high-volume mass cultures of microalgae (e.g., 18,000-L tanks), however, carbon dioxide may limit photosynthesis and growth, thereby decreasing the potential biomass of a culture. The amount of dissolved carbon in the system not only affects photosynthesis, but it can also affect the pH of the cultures. Nutrients are extremely sensitive to pH changes. For example, at a high pH, ammonia will exist predominately as unionized ammonia rather than ionized ammonium.

To investigate the chemical variability in large-volume cultures, 6 replicate 100-L kalwall tubes were inoculated with PLY429. Based upon the amount of nitrogen and phosphate added (f/2 commercial mix), all 6 algal cultures were expected to be nitrogen limited. Three cultures were bubbled with carbon dioxide so that the pH would be maintained below 9, whereas the other 3 did not receive any supplemental carbon dioxide, thus the pH could fluctuate. Cultures were incubated in a greenhouse during April of 2003. Approximately every 8 hours, samples were taken to determine dissolved inorganic carbon, alkalinity, pH, light, temperature, biomass, and particulate carbon and nitrogen. In tanks receiving carbon dioxide, final cell numbers were twice as high as in tanks that were not bubbled with carbon dioxide. The reduction in cell numbers for the tanks without carbon dioxide may be associated with low phosphate availability. In the tanks without carbon dioxide, dissolved phosphate levels became undetectable within 3 days; whereas, in the tanks with carbon dioxide, dissolved phosphate levels remained high. Phosphate can complex with other

chemicals in the media (i.e., calcium, magnesium, sodium, and iron) and render it less bioavailable for phytoplankton uptake. Phosphate complexing with these chemicals is dependent on their relative concentrations and on the pH of the media. Equilibrium calculations and our data suggest that in the cultures in which pH was not controlled (no carbon dioxide addition), phosphate may have reacted with other chemicals in the media (most likely calcium) to form a complex that was not available to the phytoplankton for growth. Thus, it seems that if pH is not controlled, resulting changes in the chemistry in large cultures of algae can influence algal growth.

SHELLFISH AQUACULTURE: THE CANARY IN THE MINESHAFT. Bill Mook, Mook Sea Farm, 321 State Route 129, Walpole, ME 04573

Mook Sea Farm has been in business for 19 years. We are located in mid-coast Maine on the Damariscotta River, where we have a 6,000 square foot hatchery and access to a little over 30 acres of oyster nursery and bottom culture leases.

In a typical year the hatchery produces more than 100 million 1 to 2 mm seed shellfish. Throughout the late 1980s and 1990s we experienced varying levels of success with our spawns, but were able to attain the desired levels of hatchery output by doing many large spawns, some of which did well enough to provide the necessary numbers of animals. We attributed the variable outcomes to the "vagaries of nature."

The "vagaries" began to get worse in 1997, but they didn't command our full attention until we started up the hatchery in 1998. Beginning with our first spawn of that year in late January, we were unable to bring a single hard clam spawn through metamorphosis. The quest for reasons began in February, and by early summer became essentially our sole focus. All of the hatchery systems were scrutinized; we hunted for a disease, and investigated the possibility of metal contamination caused by stray electrical current. By early September all lines of inquiry had led nowhere, half the company's employees had been let go, and Mook Sea Farm's future was in grave danger. Fortunately we got a tip-off: our neighbor on the river was dumping septic and porta-potty waste into the Damariscotta River near our hatchery intake.

Armed with this information we immediately started a surveillance effort. We documented the dumping, sampled the effluent and demonstrated that it produced the same effects on *Mercenaria* larvae that we had observed earlier in the year while attempting to produce seed. The ensuing regulatory and legal effort successfully shut down the illegal dumping and, beginning in 1999, Mook Sea Farm was able to produce shellfish in its hatchery again.

The experience caused us to carefully evaluate the company's goals. One of our new missions was to reach a high level of predictability in the hatchery. With good water quality and persistent effort we have achieved a high level of production efficiency

and a spawn success rate of 100% over the last 2 years. The "vagaries" seem to be safely locked in the closet.

LIPID ENRICHMENT OF EASTERN OYSTER BROOD-STOCK FOR INCREASED LARVAL SETTLEMENT. Gregg Rivara and R. Michael Patricio, Suffolk County Marine Environmental Learning Center, Cornell Cooperative Extension of Suffolk County, 3690 Cedar Beach Road, Southold, NY 11971

The link between certain fatty acids and the health of shellfish is well established. This project was designed to determine if a lipid emulsion could take the place of high lipid algal strains in the diet of oysters to maintain production while reducing the complexity and costs of operating a shellfish hatchery. Eastern oyster broodstock were fed a commercially available lipid supplement (Super Selco) designed for enriching the live feeds of finfish larvae. In one treatment, the supplement was fed in combination with T-Iso, the second feeding protocol was a high lipid strain of *Tetraselmis* and T-Iso, whereas the third was T-Iso alone (control). We measured how this supplement affected oyster broodstock conditioning in relation to fecundity, egg size, egg lipid content, and fertilization rate. In addition, we also examined late-feeding oyster larvae (before eyespot formation) as to how broodstock lipid supplementation affected set rate. Set rates of oysters fed Selco + T-Iso and *Tetraselmis* + T-Iso were higher than those fed T-Iso alone. The results of this work may be of interest to shellfish hatchery managers and remote setting operators.

This abstract is based on work supported by the Cooperative State Research, Education, and Extension Service (CSREES), US Department of Agriculture, under Agreement No. 98-38500-5917 awarded to the Northeastern Regional Aquaculture Center at the University of Massachusetts Dartmouth. Project Code 02-10.

IMPLEMENTING THE REMOTE SETTING TECHNIQUE FOR THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*, IN THE NORTH CAPE OIL SPILL SHELLFISH RESTORATION PROGRAM. Kate Ryan,¹ Karin A. Tammi,² and Michael A. Rice,³ ¹Department of Biologic Sciences, University of Rhode Island, Kingston RI 02881; ²RIDEM Division of Fish and Wildlife Coastal Fisheries Laboratory, Wakefield RI 02879; ³Dept. of Fisheries Animal and Veterinary Science, University of Rhode Island, Kingston, RI 02881.

The North Cape Shellfish Restoration Project is an attempt to repopulate the coastal ponds of Southern Rhode Island following the devastating effects of the *North Cape* Oil Spill in 1996. One major aspect of the restoration project is to repopulate the oysters in the coastal ponds. This is the first time an oyster remote set project of this size has been attempted in Rhode Island, and there are questions that need to be answered to make this project successful in the future. The focus of this study is to determine which type of locally available cultch material (surf clam, *Mactromeris*

solidissima or the ocean quahog, *Arctica islandica*) the oyster larvae prefer as a settlement substrate and to determine the growth rates of the post-set oysters in nursery trays. Remote setting of *Crassostrea virginica* larvae was carried out early on June 9, 2003 and approximately 1 million juvenile oysters on cultch materials were placed into nursery trays in Point Judith Pond on June 25. There was no statistical difference in oyster settlement onto the two substrate types. Between July 9 and October 29 mean heights of oysters on the cultch material in nursery trays increased from 5.0 to 34.0 mm, with greatest linear growth rates occurring the months of July and August. During early November 2003, oysters from the nursery trays were transported to four restoration sites in Rhode Island: Potters Cove, Spectacle Cove, Bissel Cove, and Pt. Judith Pond.

SOME IMPLICATIONS OF CONTROLLING CO₂ SUPPLY TO CULTURES OF *TETRAELMIS CHUI* (PLY429). Barry Smith and Shannon L. Meseck, USDOC, NOAA National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

The addition of carbon dioxide (CO₂) gas to marine algal cultures has been practiced by many for some time, but the quantity added is seldom matched closely to actual carbon demand. Carbon dioxide gas dissolves in seawater and dissociates to carbonic acid (CO₂+H₂O<=>H₂CO₃<=>H⁺+ HCO₃⁻). This causes a drop in pH, which can be reversed when dissolved carbon is consumed by algae during photosynthesis. Accordingly, CO₂ addition can be used to control the pH in an algal culture and to supply carbon as needed to the algae.

In April of 2003, six 100-L open cultures were started in The Greenhouse for Research on Algal Mass Production Systems (GRAMPS). The six cultures were grown in filtered seawater with Guillard's [f/2] nutrients added at time zero. Three of the cultures were not pH controlled (no CO₂ added). The other three cultures were maintained at a pH below 9.0 by daily CO₂ addition. Cultures were sampled periodically for measurements of pH, cell number, and macronutrients. The amount and time of CO₂ additions as well as weather conditions were also recorded.

Algal cultures that were controlled with CO₂ addition grew to a higher density faster than cultures that were not controlled. An average of about 1800 mL CO₂ was bubbled into each of the controlled cultures per day. The pH of uncontrolled cultures rose to over 10.0 by the 5th day. The detection of contaminants occurred at the same rate in all cultures. Further, there were no detectable differences in the blue-green algal contaminant.

The optimal amount of carbon addition should be related to the photosynthetic needs of the algae, with consideration of carbon cycling by respiration of both algae and bacteria in the culture. The optimal addition rate of carbon to the culture may be dictated by the magnitude of the resulting pH change and thus a possible physiologic shock to the algae. An automated pH monitoring and

control loop could be used to add enough carbon, in suitable doses, to satisfy algal needs and avoid large pH fluctuations. By optimizing both amount and rate of carbon addition, a control loop can be an economically desirable way to achieve higher cell densities, faster than in "traditional" static algal cultures.

A REVIEW OF GENETIC STUDIES ON COMMERCIAL SPECIES OF BIVALVES. Sheila Stiles, Joseph Choromanski, and Dorothy Jeffress, USDOC, NOAA National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

With significant advances made in the culture of marine organisms has come increased interest in improving genetic traits, especially of economic importance, such as growth, survival, and disease resistance for increased productivity. The overall goal of breeding or management of a species is to maximize productivity. An understanding of what it takes to maximize production enables the breeder or culturist to recognize signs of inbreeding depression which could be manifested as slower growth, decreased viability, disease susceptibility or overall decreased production. An example of inadequate attention to genetic consequences of culture with bay scallops occurred when some of the industry in Asia collapsed; which was attributed to inbreeding depression from a narrow gene pool.

Genetics of commercial oysters, clams, and scallops will be reviewed from such perspectives encompassing 3 aspects: breeding or quantitative genetics, chromosomal or cytogenetics, and molecular (DNA) genetics. These areas of genetics have been applied to commercial bivalves separately and in combination with varying degrees of success as measured by different responses for hatchery culture and in field programs. Conventional approaches consist of breeding methodology similar to that applied historically in agricultural genetics with the domestication of farm animals and crops. Heritability analyses of growth and selective breeding have provided positive responses in bivalves. Chromosome manipulation to induce polyploidy and cloning also has produced some favorable results. Alternatively, biotechnologic techniques can be used to facilitate progress in improvements. Various types of molecular markers are being used to supplement conventional approaches of breeding to improve characteristics with quantitative trait loci (QTLs) in marker-assisted selection (MAS). In addition, genetic markers are being used to identify stocks and to estimate genetic diversity of wild populations. DNA markers have been observed to result in variation with many alleles that could be useful for applications such as species, stock, and population identification. If environmental and habitat qualities are not suitable, however, genetic improvement in desired traits may not find ex-

pression, an important consideration for future developments in increasing the commercial production of bivalves.

THE ROLE OF DISEASE IN CONNECTICUT'S BIVALVE AQUACULTURE. Inke Sunila, State of Connecticut, Department of Agriculture, Bureau of Aquaculture, P.O. Box 97, Milford, CT 06460

There are 6 aquaculture bivalve species in Connecticut: Eastern oysters (*Crassostrea virginica*), quahogs (*Mercenaria mercenaria*), softshell clams (*Mya arenaria*), razor clams (*Ensis directus*), bay scallops (*Argopecten irradians irradians*), and blue mussels (*Mytilus edulis*). Several factors cause pathologic changes in bivalves: toxic algae, predation, fouling, salinity and temperature extremes, pollutants, hypoxia, old age, siltation, starvation, and infectious agents. Infectious agents in oysters include papovaviruses (viral gametocyte hypertrophy), Rickettsia, ciliates, *Perkinsus marinus* (Dermo), *Haplosporidium nelsoni* (MSX), *Haplosporidium costale* (SSO), *Nematopsis ostracorum*, trematodes and turbellaria. *P. marinus* and *H. nelsoni* infections are commercially important diseases. *P. marinus* prevalences were 60% to 80% between 1997 and 2002. However, the intensity of the infection (Mackin scale 1–5) remained around 1. Intensity of at least 3 is required to cause mortalities, so the high prevalence, low intensity *P. marinus* infection in oysters was not associated with significant mortalities. *H. nelsoni* caused significant mortalities in 1997–1998, but since then the epizootic prevalences have constantly decreased from the peak value of 47% in 1997 to 3% in 2002. Oyster production was low despite the low disease prevalences. Factors other than disease regulated oyster stocks in CT. Unlike southern estuaries, successful oyster sets in CT do not occur yearly, but several years apart. Commercial oyster sets occurred in 1969, 1973, 1987, and 1997. No sets have occurred since 1997 and commercial oyster inventory is low. The proportion of hatchery raised oysters in CT's production is presently only 4%. Quahog production is increasing and CT is the number one quahog producer on the East Coast. Infectious agents in quahogs include *Perkinsus* sp., *Chlamydia*, and QPX (Quahog Parasite Unknown, Labyrinthulomycota, Thaumochytridae). QPX, an economically important clam parasite, had a prevalence of 0.2% (3 out of 1764 clams studied in 1997–2003) and doesn't presently pose a threat to CT's quahog harvest. Infectious agents in softshell clams include *Perkinsus* sp. and the agent causing disseminated sarcoma, presumably a retrovirus. Infectious agents in bay scallops include trematodes and kidney coccidia. Infectious agents in blue mussels include *Chlamydia*, *Ancistrum mytili* ciliates, the microsporidian *Steinhilfsii mytilovum* (Mussel Egg Disease) and the trematode *Proctoeces maculatus*. *S. mytilovum*, and *P. maculatus* are economically important mussel parasites that pose a threat to potential CT mussel aquaculture. Although the list of infectious agents in CT's bivalves is extensive, parasite pressure alone doesn't restrict possible expansion of bivalve aquaculture. The most important biologic factor

currently posing a threat to the industry is the increasing occurrence of toxic algae blooms.

INDUCED TRIPLOIDY IN THE BAY SCALLOP, ARGOPECTEN IRRADIANS IRRADIANS, AND FIELD CULTURE PERFORMANCE. Amandine S. Surier and Richard C. Karney, Martha's Vineyard Shellfish Group, PO Box 1552, Oak Bluffs, MA 02557

Triploidy is the condition of possessing three times the haploid number of chromosomes in the cell nucleus. It can be induced by cell treatment, in the early stages of development. Not to be confused with controversial, transgenic genetically-modified organisms (GMOs), polyploidy is simply an increase in the number of a single organism's chromosomes, with no introduction of foreign genetic material. Triploid animals and plants are usually sterile because of the inability of homologous chromosomes to synapse in meiosis. As a result of their sterility, they tend to divert the energy usually used for reproduction towards somatic growth. Because of this unique quality, triploid bivalve production has attracted worldwide attention since the early 1980s. At present triploidy has been successfully applied to the economic benefit of the Pacific oyster industry on the west coast of the United States and also in France.

Triploidy in scallops has been investigated in several species over the past 20 years. Overall, research suggests that the development of a triploid bay scallop will result in an increased growth rate, a larger adductor muscle mass and an increased hardness with regard to stressful environmental conditions.

To test this hypothesis, triploidy was induced in the bay scallop *Argopecten irradians irradians*, under funding from the Northeastern Regional Aquaculture Center. The newly fertilized eggs were treated with a low risk chemical, 6-DMAP, that has been shown to be slightly less efficient than Cytochalasin B but much safer to handle as well as water soluble. The success of induction was measured by flow cytometry at the Virginia Institute of Marine Science. Triploidy was induced on five occasions during the 2003 culture season. Each batch of eggs was treated 15 to 25 minutes post fertilization for approximately 11 minutes with a treatment concentration of 400 μ M. The results ranged from 77% up to 97% triploidy in the first week of development. In late August and early September, juveniles from the last two spawns were deployed in growth trials in Katama Bay on Martha's Vineyard, MA, Buzzards Bay on Cape Cod, MA, in Point Judith Pond, RI, and in several bays on eastern Long Island. The shell growth was measured every 2 weeks at each site until the end of the growing season.

COMMUNAL EFFECTS BETWEEN ARGOPECTEN IRRADIANS IRRADIANS AND NASSARIUS OBSOLETUS. David J. Veilleux and Katlyn Mihalek, USDOC, NOAA National Marine Fisheries Service, USDOC, NOAA Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Groups of bay scallops, *Argopecten irradians irradians*, and mud dog whelks, *Nassarius obsoletus*, were placed in pearl nets to

test if the presence of the snails would control biofouling and reduce sedimentation within the suspended culture gear. The nets were hung for 33 days to attain settlement of the fouling communities and the level of sediments common to aquaculture gear. We compared survival and growth of scallops in treatments ($n = 2$) with and without the presence of snails. The wet weights and shell heights were measured for all animals at the start and finish of the experiment. Scallop wet weight averaged 32 g greater in treatments containing snails compared with those without snails. This increase in weight may be attributed to the snail's ability to clear the mesh of fouling, therefore increasing water flow rates to the scallops. The results from this trial suggest that this simple low-cost approach may improve aquaculture productivity.

GROWTH ENHANCEMENT OF DISEASE-RESISTANT STRAINS OF THE EASTERN OYSTER THROUGH TRIPLOIDY. Yongping Wang, Ximing Guo, Gregory DeBrosse and Susan Ford, Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349

The eastern oyster (*Crassostrea virginica*) faces three major diseases: MSX (caused by the parasite *Haplosporidium nelsoni*), Dermo (caused by the parasite *Perkinsus marinus*), and the juvenile oyster disease (JOD, probably caused by a bacterium). Rutgers University has been breeding oysters for disease-resistance since the early 1960s. Strains resulting from the Rutgers breeding program have shown strong resistance to MSX and recently some resistance to Dermo. Whereas the Rutgers strains are superior in disease-resistance, they do not grow as fast as some of the commercial strains, such as the Frank M. Flower Oyster Company's strain. Growth improvement of the Rutgers disease-resistant strains is needed to maximize return for oyster farmers. Triploids grow significantly faster than diploids in most mollusks studied so far. We recently developed tetraploid oysters from the Rutgers disease-resistant strains. The goal of this study is to produce mated triploids from the disease-resistant tetraploid stocks and compare their growth and survival to that of normal diploids and chemically induced triploids.

Three replicates of 3 groups were produced from Rutgers disease-resistant stocks: (1) diploid control (2N); (2) triploids induced by blocking polar body II with cytochalasin B (3nCB); and (3) natural triploids produced by diploid female \times tetraploid male crosses (3nDT). The 3nCB groups produced 72% triploids on average, and the 3nDT groups produced 98% triploids. Oysters were measured and individually assayed for ploidy confirmation. At 17 months of age, oyster size was in the general order of 3nDT > 2n > 3nCB. Triploids from 3nDT were significantly bigger than 2N diploids and 3nCB triploids in shell height, and significantly bigger than 2N diploids in whole body weight. Preliminary results from this study suggest that mated triploids may provide significant growth enhancement over diploids and chemically induced triploids.

EFFECTS OF 96-HOUR EXPOSURE TO AMMONIA ON BAY SCALLOPS, *ARGOPECTEN IRRADIANS IRRADIANS*. James C. Widman Jr., Shannon L. Meseck, George Sennfelder and David J. Veilleux, USDOC, NOAA National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

In either static, semi-static, or recirculating culture systems nitrogenous waste products are produced by bay scallops, *Argopecten irradians irradians*, during their normal metabolic activities. The toxic components of these waste products need to be controlled or converted to less lethal forms or they will result in scallop mortalities. Little research has been done to determine the lethal concentrations of un-ionized ammonia in juvenile bay scallops (<30 mm). The ratio of ammonia in the ionized and un-ionized form (with the latter being the toxic form) is dependent on pH, temperature, and salinity.

In this experiment, salinity and temperature remained constant while pH (7.6, 8.0, and 8.4) and ammonia levels (0, 6, 12, and 18 mg N L⁻¹) were varied resulting in a 3 \times 4 grid. Scallops were not fed during the 96-hour exposure to ammonia to prevent uptake by phytoplankton. Un-ionized ammonia concentrations ranged from 0 mg to 5 mg L⁻¹. At un-ionized ammonia concentrations greater than 0.60 mg L⁻¹ we observed 100% bay scallop mortality. Un-ionized ammonia concentrations of approximately 0.45 mg L⁻¹ resulted in 50% scallop mortality. At a pH of 8.4 total ammonia concentrations as low as 6 mg L⁻¹ resulted in 100% scallop mortality. Monitoring of ammonia and pH is vital to maintaining high survival in static and recirculating scallop rearing systems.

DETERMINING OPTIMUM FEEDING CONCENTRATIONS FOR BAY SCALLOPS, *ARGOPECTEN IRRADIANS IRRADIANS*, USING AN AUTOMATED CONTROL SYSTEM. James C. Widman Jr. and David J. Veilleux, USDOC, NOAA National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Technologic changes over the last 30 years allow us to make new observations into the filter feeding behavior of bay scallops, *Argopecten irradians irradians*. We have developed an automated feeding system that uses a fluorometer to monitor the fluorescence of phytoplankton suspended in culture water as an indication of cell concentration. Fluorometer readings are acquired by a personal computer and input to an algorithm that can: (1) terminate the addition of algae; (2) start the addition of algae; and (3) continue at the present feeding status. This system allows us to quan-

tify the frequency and duration of feeding in a semi-static closed culture system.

A series of range finding experiments were conducted with bay scallops to explore optimum feeding concentrations and growth. All experiments were conducted at 24°C using 10 µm filtered seawater. During trial one, scallops were grown in seawater with *Tetraselmis chui* (PLY429) concentrations of 15,000, 25,000, 35,000, and 45,000 cells/mL. Scallops ranging in initial mean shell heights of 6.7–7.1 mm grew to 9.2–9.9 mm in 28 days with no significant difference ($P > 0.05$) in growth. In the second trial, scallops were grown in seawater with *Tetraselmis chui* PLY429 concentrations of 5,000, 10,000, 15,000, and 25,000 cells/mL. Scallops ranging in initial mean shell heights of 6.6–7.1 mm grew to 12.8–13.2 mm in 23 days with no significant difference ($P > 0.05$) in growth. In the third trial, scallops were grown in seawater with *Tetraselmis chui* (PLY429) concentrations of 1,000, 2,333, 3,667, and 5,000 cells/mL. Scallops ranging in initial mean shell heights of 5.8–6.2 mm grew to 13.6–14.8 mm in 36 days. We found a significant difference ($P < 0.05$) in growth of bay scallops held at these concentrations. Scallops grown at 2,333 cells/mL were similar to those grown at 1000 cells/mL and significantly larger than those grown at higher cell concentrations.

These preliminary results indicate that growing scallops at low phytoplankton concentrations yields faster growth. Scallop growth in our experiments was optimized at 2,333 cells/mL, but further studies will refine the relationship between cell concentration and optimal growth.

THE ESTUARINE DINOFLAGELLATE, *PROROCENTRUM MINIMUM*—“HAB” OR “HAB-NOT?” Gary H. Wikfors,¹ Jennifer H. Alix,¹ Roxanna M. Smolowitz² and Hélène Hégaret³, USDOC, NOAA ¹National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; ²Marine Biological Laboratory, Woods Hole, MA 02543; ³Department of Marine Sciences, University of Connecticut, Groton, CT 06340

Field observations and laboratory studies showing a variety of harmful effects of *Prorocentrum minimum* upon molluscan shellfish have not resulted in a consensus on whether *P. minimum* “is toxic” to grazing molluscs. Mortalities of marine life coincident with natural blooms of *P. minimum* sometimes seem to be associated with resultant hypoxia, but not always. Laboratory experiments testing the response of grazing molluscs to *P. minimum* cultures have yielded variable results, ranging from mortality to normal growth, and including rejection as pseudofeces, poor development, tissue pathologies (sometimes transient), and systemic immune responses. The variability in trophic interactions between *P. minimum* and molluscan shellfish suggests variation in the expression of “toxicity” in this species, although a specific chemical compound has not been identified as “the toxin.” Several recent studies have provided strong evidence that variation in toxicity is dependent upon environmental conditions and their effects upon the physiology of *P. minimum*. Accordingly, seemingly conflicting observations from field and laboratory studies may be explained by the transient nature of toxin expression in this dinoflagellate.

ABSTRACTS OF TECHNICAL PAPERS

ASSESSING THE IMPACTS OF URBANIZATION ON SHELLFISH GROWING AREAS IN PUGET SOUND.

Marina Alberti, Department of Urban Design and Planning, University of Washington, Box 355740, Seattle, WA 98195; **Marcie Demmy Bidwell**, Department of Landscape Architecture, University of Washington, Box 355740, Seattle, WA 98195; and **Stuart Glasoe**, Puget Sound Action Team, Office of the Governor, PO Box 40900, Olympia, WA 98504-0900.

Shellfish are prized icons of the Pacific Northwest, associated with many recreational, cultural, and economic values. Clean water is essential for shellfish harvesting. However, an increase in human population and development within near-shore environments and adjacent watersheds has negatively impacted water quality, resulting in increased closures of fishing, contact recreation, and shellfish harvesting. Though research has shown that urbanization alters water quality through changes in reduced native vegetative cover, increased impervious surfaces, altered hydrology, and other impacts, the relationships between patterns of urbanization and shellfish growing areas are poorly understood. We developed an empirical analysis of 32 basins in Puget Sound with variable degrees of urbanization to test the formal hypotheses regarding the impact of urban patterns on shellfish growing areas. The sites were selected to represent a gradient of urban land use/land cover patterns. Our working hypothesis is that variations in land cover composition, landscape configuration, and connectivity of impervious areas explain most of the variation in near-shore water quality conditions. Using bacterial contamination as the indicator of near-shore conditions, we develop a comparative or cross-sectional analysis across the 32 basins to assess what landscape factors best explain water quality conditions in Puget Sound's shellfish growing areas. We discuss the implications of our results and recommendations to policymakers and resource managers within the Puget Sound region.

RECENT MORTALITY EVENT OF PACIFIC RAZOR CLAMS, *SILIQUA PATULA*, ALONG THE PACIFIC COAST OF WASHINGTON STATE ASSOCIATED WITH RECORD INFECTION INTENSITY OF THE GILLS BY NUCLEAR INCLUSION X (NIX).

Dan L. Ayres, Washington Department of Fish and Wildlife, Montesano, WA 98563; **Ervin J. Schumaker**, Quinalt Department of Natural Resources, PO Box 189, Taholah, WA 98587; and **Ralph Elston**, Aquatechnics, PO Box 687, Carlsborg, WA 98324.

After the summer 2002 razor clam stock assessment, a record number of adult razor clams were determined to be available for harvest on the five management beaches located along the Washington State coast. However, due to high levels of the marine toxin domoic acid, no harvest occurred on any management beach with the exception of a limited tribal harvest on the northern beaches before the toxin arrived. Coincidentally, a sample of 50 clams was collected in early October for analysis of infection intensity of

nuclear inclusion X (NIX). NIX is a primitive, large bacterium obligately infecting the nucleus of gill epithelial cells of the razor clam. NIX is a member of the gamma subclass of the eubacterial class Proteobacteria. NIX was the suspected cause of a razor clam mortality event in 1983 that resulted in the loss of more than 90% of the adult clams found on some management beaches as well as high percentage losses in 1985 and 1989 associated with high NIX infection intensities. The high NIX infection intensities are followed by ruptured gill epithelia that may be synchronized by an environmental temperature drop. In October 2002, we found an average NIX infection intensity of 48.3, the highest ever recorded since records were first made in 1983. The summer 2003 razor clam stock assessment found a 49.7% loss of adult clams coast-wide. NIX is again the likely suspect.

STATUS OF THE EUROPEAN GREEN CRAB INVASION.

Sylvia Behrens Yamada and **Marsha Becklund**, Zoology Department, Oregon State University, Corvallis, OR 97331.

The recent invasion of Pacific Northwest estuaries by the European green crab, *Carcinus maenas*, caused much initial alarm. Following the strong El Niño of 1997–1998, young green crabs appeared in estuaries along the coasts of Oregon, Washington, and as far north as Nootka Sound on the west coast of Vancouver Island, British Columbia. Unusually strong northward-moving coastal currents of up to 50 km/day must have transported larvae from more established populations in California to the Northwest. Coastal transport events have been much weaker in recent years. Crabs from the 1997–1998 colonizing year class are still in the population. Males now range from 86 to 98 mm in carapace width. We predict that most of the colonizing year class will die of senescence by the end of 2004. Though we have trapped young green crabs (less than 50 mm in carapace width) in 1999–2003, their abundance has been at least one order of magnitude lower than in 1998. Lack of larval supply appears to prevent green crabs from expanding their range at this time. We predict that favorable ocean conditions, associated with strong El Niño events, will result in an increase in green crab abundance and range expansion. Even though green crab abundance in the Northwest is low when compared with Europe, eastern North America, and California, it is imperative to continue monitoring efforts to elucidate the process of range expansion of non-indigenous marine species and to serve as an early warning system for the next strong recruitment event of green crabs.

DEVELOPMENT AND IMPLEMENTATION OF AN IPM PROGRAM FOR BURROWING SHRIMP IN WILLAPA BAY/GRAYS HARBOUR, WASHINGTON.

Steven Booth, Willapa Bay-Grays Harbor Oyster Growers Association, Nahcotta, WA 98637; and **Bill Dewey**, Taylor Shellfish, Shelton, WA 98584.

In March 2003, a "Comprehensive plan towards an integrated pest management program for burrowing shrimp on commercial oyster beds" was submitted to the Washington Department of

Ecology. The plan was comprehensive as it included descriptions of relevant concepts, definitions and goals, references, lists of principal authorities and policies, and five interconnected key IPM elements: (1) funding, (2) research & development, (3) implementation, (4) evaluation/regulatory compliance, and (5) dissemination. Yet the plan remains incomplete within each element. It remains "a living document" as directed in the original Memorandum of Agreement between the Growers Association and several state agencies that mandated its development in 2001. Here, we present the recent (post-2001) history of the IPM plan for burrowing shrimp and its potential future(s) within the web of environmental, political, and agricultural concerns. The plan itself is described with special consideration given to how well it corresponds to the traditional IPM paradigm adopted for terrestrial agroecosystems.

BIOCHEMICAL AND HISTOLOGIC CHANGES IN RED ABALONE (*HALIOTIS RUFESCENS*) SUBJECTED TO DIFFERENT COMBINATIONS OF TEMPERATURE, FOOD AVAILABILITY, AND INFECTION WITH THE AGENT OF WITHERING SYNDROME. **Beverly A. Braid, James D. Moore, Thea T. Robbins, Ronald P. Hedrick,** School of Veterinary Medicine, University of California, Davis/Bodega Marine Laboratory, Bodega Bay, CA 94923; **Ronald S. Tjeerdema,** Department of Environmental Toxicology, University of California, Davis, CA 95616; and **Carolyn S. Friedman,** School of Aquatic and Fishery Sciences, University of Washington, Seattle, WA 98195.

We conducted a long-term study to identify pathophysiologic changes that occur during progression of withering syndrome (WS) and to contrast these with changes due to starvation in uninfected animals. Following antibiotic treatment to assure all animals were free of the bacterial agent of WS (WS-RLP), farmed red abalone were subjected to eight separate treatment combinations of exposure to WS-RLP (exposed or unexposed), temperature (ambient or 19°C), and food availability (fed or starved). The digestive gland (DG) retained up to 186 ppm oxytetracycline at day 105 post-treatment. Though 0.1% of abalone sampled from exposed/ambient groups became infected over 497 days, 56% of abalone sampled from exposed/19°C groups became infected. Metaplastic DG changes occurred only in infected abalone. Metaplastic DG did not exhibit proliferation or apoptosis differing from normal DG. Abalone in the exposed/fed/19°C treatment had significantly more DG changes and infection intensities than those in the exposed/starved/19°C group ($P < 0.05$). Foot glycogen decrease preceded shrinkage, foot degeneration, and decrease in condition index. Progression of WS shared many features with starvation although changes in DG architecture appear pathognomic for this disease. Supported by California Sea Grant College Program award R/A 117 and the Marine Region, California Department of Fish and Game.

THE EFFECTS OF LARVAL DISPERSAL ON GENETIC STRUCTURE OF BLACK ABALONES (*HALIOTIS CRACHERODII*). **Melinda D. Chambers, Carolyn Friedman, Lorenz Hauser,** School of Aquatic and Fisheries Sciences, University of Washington, Seattle, WA 98195; and **Glenn R. VanBlaricom,** Washington Cooperative Fish and Wildlife Research Unit, School of Aquatic and Fisheries Sciences, University of Washington, Seattle, WA, 98195.

Populations of black abalone have experienced declines of 85–99% throughout their range since the emergence of the bacterial pathogen causing Withering syndrome (WS) in 1985. Recovery of the species throughout its original range will depend on the ability for the remnant population to recruit successfully. The recruitment of organisms with a pelagic larval stage depends on oceanic physics coupled with larval characteristics of the species. It is thought that a high rate of larval dispersal could reduce the survival rate of a species recovering from depleted densities due to predation, starvation, or transport away from suitable habitat. A drift card study of sea surface circulation and a population genetics assessment was conducted to identify recruitment potential of black abalones throughout the California offshore islands. Drift cards were released from San Nicolas Island, California, in August 2002 and June 2003 corresponding with the two peaks in the spawning season of the species. Results indicate that free-floating surface particles are locally retained. To identify population structure of the species resulting from the dispersal of larvae, tissue was collected for genetic analysis from abalones on Santa Cruz, Santa Rosa, San Miguel, and San Nicolas Islands as well as from Vandenberg and Monterey on the California mainland. Results indicate that isolated populations are not significantly genetically differentiated but that genetic distance corresponds with geographic distance. Additionally, populations of recruit-sized individuals are more highly structured than adults at the same locations.

FOULING ORGANISM (*TRITICELLA* SP.) OF THE SPOT SHRIMP *PANDALUS PLATYCEROS*. **Richard K. Childers,** Washington Department of Fish and Wildlife, Point Whitney Shellfish Laboratory, Brinnon, WA 98320; **Ralph A. Elston,** Aquatechnics, Sequim, WA 98382; and **Judy Winston,** Virginia Museum of Natural History, Martinsville, VA 24122.

A *Triticella* sp. (Bryozoa) was first observed as a fouling organism on the carapace of spot shrimp *Pandalus platyceros* in Hood Canal Washington in the fall of 2002. The prevalence and geographic distribution of the parasite on spot shrimp were studied and prevalence was analyzed by size, sex, and location of the shrimp. A total of 1931 shrimp were examined from twelve locations in Puget Sound. Prevalence of the parasite was high in shrimp from most locations sampled, ranging from a low of 0% (Port Townsend Bay) to 89% (Quilcene Bay), with an overall prevalence of 66%. The high prevalence of the fouling organism was associ-

ated with displacement of shrimp from their normal deep water habitat to shallow water during a period of low dissolved oxygen in Hood Canal, Washington. Large numbers of the bryozoan colonies were anchored to the carapace of the shrimp, particularly at articulations of carapace plates but also to appendages, except antennae. The colonies consisted of tufts of dense white stolons and zooids with spots of yellow brown coloration representing ingested algal cells. The bryozoans were not found attached to any soft tissues, but the sheer mass of attached organisms may have interfered with normal respiration and movement of the shrimp. Eleven species of the genus *Triticella*, typically epizootic on decapod crustaceans, have been named. Those found on the nektonic spot shrimp appear to represent an undescribed species, based on length and width of the zooids and stolon.

PREVALENCE, GEOGRAPHIC DISTRIBUTION, AND BIOLOGY OF A DUNGENESS CRAB, *CANCER MAGISTER*, MICROSPORIDIAN PARASITE. Richard K. Childers, Washington Department of Fish and Wildlife, Point Whitney Shellfish Laboratory, Brinnon, WA 98320; Paul W. Reno and Robert E. Olson, Oregon State University, Hatfield Marine Science Center, Newport, OR 97356.

The prevalence and geographic distribution of *Nadelspora canceri*, a microsporidian parasite of the Dungeness crab *Cancer magister*, was studied and prevalences were analyzed by sex and size of host and date of collection. *Nadelspora canceri* was widely distributed along the U.S. Pacific Coast in estuaries from Bodega Bay, California, to southern Washington. Prevalence of the parasite was high in crabs from most estuaries sampled between 1991 and 1994, ranging from a low of 0.4% (Gray's Harbor, Washington) to 41.2% (Tillamook Bay, Oregon) with an overall mean of 14%. Crab examined from Grays Harbor in 2002 indicate the prevalence rate had increased from 0.4% to greater than 4%. The parasite also occurred offshore of California and Oregon, but was not found in Puget Sound, Washington, or in Glacier Bay, Alaska. The prevalence of infection in crabs captured in the open ocean was low (0.3%). In crabs collected near-shore at estuary mouths, prevalence was intermediate between estuarine and open-ocean levels. The infection was most prevalent in 2-y-old crabs (13-cm carapace width), and males had 2.5 times the rate of infection than did females. The mortality of laboratory-held crabs naturally infected with *N. canceri* was compared with that of uninfected crabs, and significantly higher mortality was observed for infected crabs. *Nadelspora canceri* infections were established in juvenile and adult crabs that were fed parasite spores in laboratory experiments indicating that transmission is direct and intermediate hosts or vectors are not required for transmitting the parasite.

THE RATE OF PREY CONSUMPTION IN TWO ESTUARINE CRAB SPECIES: THE INTRODUCED EUROPEAN GREEN CRAB, *CARCINUS MAENAS*, AND NATIVE DUNGENESS CRAB, *CANCER MAGISTER*. Timothy M. Davidson and Sylvia Behrens Yamada, Environmental Science Department and Zoology Department, Oregon State University, Corvallis, OR 97331-2914.

The European green crab (*Carcinus maenas*) is a voracious predator responsible for declines in numerous bivalve populations around the world. To predict the relative impact of *C. maenas* on bivalve prey in the Pacific Northwest, we compared prey consumption rates, claw morphology, and claw strength of *C. maenas* and the native Dungeness crab (*Cancer magister*). Field trials were conducted in a tidal channel from September 2, 2002, to September 14, 2002. Similar sized crabs were individually caged in sealed minnow traps and offered 50 mussels (*Mytilus trossulus*) (25–35 mm) per trial. Trials ranged from 48 to 72 h. After each trial, the numbers and biomass of consumed and partially consumed mussels were recorded. Both *C. maenas* and similar sized *C. magister* ate around 15 g of mussel meat per day. Though *C. maenas* and *C. magister* exhibit similar consumption rates, differences in claw morphology may allow the introduced crab to have a stronger effect on bivalve populations. *C. maenas* possess several superior claw characteristics including dimorphism, higher mechanical advantage of the claw lever system, and significantly larger propal heights in the master claw. These characteristics suggest that *C. maenas* has greater claw strength than *C. magister* and thus the ability to exploit larger and thicker shelled bivalves.

IMPLEMENTING A MONITORING PROGRAM FOR BURROWING SHRIMP AS PART OF AN INTEGRATED PEST MANAGEMENT PROGRAM IN WILLAPA BAY AND GRAYS HARBOR, WASHINGTON. Brett Dumbauld, Washington State Department of Fish and Wildlife, Willapa Bay Field Station, Ocean Park, WA 98640; D. Cheney, A. Suhrbier, H. Beltran, Pacific Shellfish Institute, Olympia, WA 98195; S. Booth and D. Tufts, Willapa Bay-Grays Harbor Oystergrowers Association, Nahcotta, WA 98637.

Two species of burrowing thalassinid shrimp cause significant problems for oyster aquaculture in West Coast estuaries by undermining the substrate that oysters grow on. An annual control program that uses the pesticide carbaryl applied directly to the estuarine mudflat has taken place in Washington State since 1963. The pesticide application program continues to be controversial, and the oystergrowers signed a memorandum of agreement with several state agencies and others in 2001 that requires that integrated pest management be pursued. In a recent out-of-court settlement, the growers also agreed to reduce and eventually stop carbaryl use. We designed and implemented a monitoring plan for burrowing shrimp in Willapa Bay and Grays Harbor, Washington, during 2002–2003. Monitoring plans are an integral part of any pest man-

agement plan, but monitoring shrimp populations in an estuarine setting is particularly challenging. Shrimp burrow deeply in the sediment, and pest abundance must be assessed by counting highly variable burrow openings that are difficult to distinguish from those of other organisms. Shrimp also display highly variable interannual recruitment patterns and oysters are planted on a two- to four-year schedule and therefore are akin to a perennial terrestrial crop. The data we collected and present suggest that monitoring is beneficial and that it may reduce costs and better target pest control efforts, regardless of the control tactic being used.

STATUS, PREVENTION AND MANAGEMENT OF DENMAN ISLAND DISEASE IN WASHINGTON STATE. Ralph Elston, Aquatechnics and Pacific Shellfish Institute, PO Box 687, Carlsborg, WA 98324.

Denman Island disease, caused by the protistan parasite, *Mikrocytos mackini*, was found for the first time in Washington State in May 2002. Surveillance continuing into 2003 confirms the infection of Pacific oysters in seven locations. The disease is considered to have no significance for Pacific oyster farming in British Columbia in most cases, with the exception of a few locations where three-year-old oysters are affected. Findings in Washington have been at low prevalence and often without visible pustular lesions, usually in larger feral oysters. The disease is known to be expressed at cooler water temperatures (ca. 10°C). Other species of oysters are susceptible to infection. The disease has significance to exporters of live shellfish products because it is considered a notifiable disease by the Office Internationale Epizooties (OIE). Most export producers have established a history of health surveillance and certification showing absence of the disease in brood and seed stocks. In conjunction with Canadian collaborators, we are conducting a risk analysis and risk management process and will recommend whether the disease should be listed as a notifiable disease to the OIE. Though there are some risks from this disease, other oyster diseases, both notifiable and not notifiable to the OIE, have clearly greater health consequences to the known host oyster. The primary risk to Pacific oysters may be in colder climates, although Washington seed oyster producers have been supplying oyster seed to Alaskan shellfish farms and there have been no reports of the disease in that state.

PROGRESS IN THE DEVELOPMENT OF EFFECTIVE PROBIOTIC BACTERIA FOR BIVALVE SHELLFISH HATCHERIES AND NURSERIES. Ralph Elston, Karen Humphrey, Aquatechnics, PO Box 687, Carlsborg, WA 98324; Arthur Gee, Daniel Cheney and Jonathan Davis, Pacific Shellfish Institute, Olympia, WA 98501.

We tested the efficacy of multiple probiotic bacterial candidates to protect Pacific oyster (*Crassostrea gigas*) larvae and juveniles against challenge by bacterial pathogens and to increase

survival of unchallenged hatchery-produced larvae. Probiotic bacterial strains were local isolates. In 12 replicated well plates and in scaled-up 1-L cultures of oyster larvae challenged with *Vibrio tubiashii*, with and without probiotic candidate P02-45 added at a concentration of 10^5 cfu per mL, survival of larvae was typically 40–80% greater in cultures with probiotic added. Addition of probiotic P02-45 to unchallenged hatchery production batches of larvae resulted in a survival improvement as great as from 21.0% without probiotic to 76.5% with probiotic. *In vitro*, both killed bacteria and cell-free extract were effective pathogen inhibitors. Compatibility of probiotic candidates P02-45 and P02-1 with seven species of algal food was determined. Probiotic candidates were compatible with some algal foods and, in some cases, resulted in an increased density of algal cells. Two compatible species were Tahitian *Isochrysis* sp. and *Rhodomonas* sp. Addition of algal cultures containing probiotic bacteria provided protection for larvae challenged with *Vibrio tubiashii* and a new filamentous bacterial pathogen. The probiotic was safe for oyster and other species of shellfish larvae up to a concentration of 10^7 cfu/mL. Above this concentration, the larvae appeared to die of anoxia due to the high bacterial concentration. Research supported by grant project number 2002-00362 from the U.S. Department of Agriculture, C.S.R.E.E.S., Small Business Innovation Research program.

THE EFFECTS OF NURSERY ENVIRONMENT ON THE PERFORMANCE OF ADULT PACIFIC OYSTERS *CRASSOSTREA GIGAS*. Ford Evans and Chris Langdon, Coastal Oregon Marine Experiment Station, Hatfield Marine Science Center, Department of Fisheries and Wildlife, Oregon State University, Newport, OR 97365.

A study was conducted to determine whether the rank-order of average family performance at harvest (2+ years old) was significantly altered by the feeding regimen that they experienced in the nursery as spat. Five full-sib oyster families were created and reared three different feeding regimes during the nursery phase. Forty individuals from each family-nursery treatment combination were stocked into each of 10 replicate lantern net tiers and deployed subtidally in Yaquina Bay, Oregon. Measurements of yield, individual weight, and survival were recorded after one and two growing seasons. Average family yield after two growing seasons was significantly affected by genotype ($P < 0.01$) but not by nursery environment ($P = 0.10$) or genotype \times nursery environment interaction ($P = 0.89$). Components of yield (i.e., individual growth rate and survival) were affected by both genotype and nursery environment ($P < 0.01$) but not genotype \times nursery environment interaction ($P > 0.82$). These results suggest that variation in nursery environment, manipulated by feeding regimen, does not significantly alter the rank-order of average family yield, growth rate, and survival evaluated after two growing seasons in the field.

BIOLOGY AND FISHERIES OF THE EXOTIC VARNISH CLAM (*NUTTALLIA OBSCURATA*) IN BRITISH COLUMBIA. Graham E. Gillespie and Neil F. Bourne, Fisheries and Oceans Canada, Pacific Biologic Station, Nanaimo, BC, Canada V9T 6N7.

Varnish clams, *Nuttallia obscurata*, have recently become established in southern British Columbia. They continue to expand beyond the Strait of Georgia into Johnstone Strait to Port Hardy and northwards along the west coast of Vancouver Island to Brooks Peninsula. They will likely become established in the Central Coast, although taking a different route than Manila clams. Experiments to examine competitive relationships between Manila and varnish clams showed evidence of competition when the two were placed together, with varnish clams having some advantage in the upper intertidal and Manilas in the mid-intertidal zone. Histologic examination revealed one spawning event per year, in July and August. Gonadal development started in January, and most clams were partially spent or inactive after September. Some clams in their second summer (~15–17 mm TL) showed evidence of early development of gonadal tissue, but most active spawners were greater than 25-mm TL, indicating that effective spawning commences two years after settlement. Varnish clams >30-mm TL were harvested from mixed populations, with harvest efficiency ~60–80% for this size class. Breakage during harvest was ~2%, and shrinkage during processing was ~4%, evenly divided between mortality and weight decrease due to water loss. Grit was purged readily within 48 h of wet storage, but commensal pea crabs were not purged after 34 days. Varnish clams have been added to aquaculture permits in BC, and most commercial harvest comes from leases. Commercial fisheries have not yet been successful.

THE EXPANSION OF AN INVASIVE CORDGRASS (*SPARTINA ALTERNIFLORA*) RESULTS IN THE LOSS OF CRITICAL FORAGING HABITAT FOR DUNGENESS CRAB (*CANCER MAGISTER*) IN WILLAPA BAY, WASHINGTON. Kirsten K. Holsman and P. Sean McDonald, School of Aquatic and Fishery Sciences, University of Washington, Seattle, WA 98195.

Tidally driven migrations are an integral component of the life histories of many brachyuran species, allowing crabs to use productive intertidal habitats at high tide and subtidal refuges at low tide. Results of a bioenergetic model for crabs in Willapa Bay, Washington, indicated that intertidal foraging is an essential element of the estuarine life history of *Cancer magister*, contributing significantly to the energy budget of subadult crabs (40–130 mm; 1+ and >1+ year classes), and likely facilitating the high abundances observed in large coastal estuaries. Acoustic telemetry studies and underwater video observations have shown that subadult *C. magister*, which reach densities as high as 4300 crabs ha⁻¹ in subtidal channels during low tides, regularly migrate during flood tides into intertidal habitats to forage. Furthermore, these

studies, as well as results of baited trapping surveys, revealed that subadult crabs are most abundant in unvegetated open sand or mud habitats at high tide. However, these habitats are increasing colonized by the invasive cordgrass *Spartina alterniflora*. Trapping surveys have shown that subadult crabs do not use *S. alterniflora* beds, and the rapid conversion of critical foraging habitats into inaccessible *S. alterniflora* patches threatens to significantly reduce crab populations within Willapa Bay. Because estuarine production of *C. magister* is a major contributor to the coastal population of adult crab, *S. alterniflora* expansion could potentially impact the coastal fishery.

THE EFFECT OF *ZOSTERA MARINA* AND *CRASSOSTREA GIGAS* CULTURE ON INTERTIDAL COMMUNITIES IN A NORTHEAST PACIFIC ESTUARY. Geoff Hosack, David Armstrong, School of Aquatic and Fishery Sciences, University of Washington, Seattle, WA 98195; Brett Dumbauld, Washington State Department of Fish and Wildlife, Willapa Bay Field Station, Ocean Park, WA 98640; Jennifer Ruesink, Brice Semmens, Department of Zoology, University of Washington, Seattle, WA 98195; and Ian Fleming, Department of Fisheries and Wildlife, Oregon State University, Newport, OR 97365.

Intertidal habitat structure created by seagrass and oysters is broadly considered to play an important role in the shaping of many biologic communities. In Pacific Northwest estuaries, commercial oysters are often cultivated at the same tidal elevation as seagrass meadows, and thus management decisions concerning resource use require insight into their comparative value. We compared the use of three important habitats by fish and crab within the low intertidal zone of Willapa Bay, Washington: (1) seagrass meadow (*Zostera marina*), (2) unvegetated tideflat, and (3) commercial oyster ground culture (*Crassostrea gigas*). We also sampled epibenthic meiofauna as a potential source of prey for fish and crab. Using passive gear (hoop nets) in 2001, we found no relationship between total CPUE or composition of nekton. Concurrent sampling with an epibenthic pump, however, showed that habitat has a strong effect on meiofaunal communities. Meiofauna densities were more than seven times higher in structured habitats, and composition was significantly affected by habitat. In 2002 and 2003, we focused on outmigrating juvenile chinook, chum, and coho salmon (*Oncorhynchus tshawytscha*, *Oncorhynchus keta*, and *Oncorhynchus kisutch*) using a modified tow net in the above habitat types plus adjacent subtidal channels. There was no evidence of a habitat effect, although region (within estuary) explained a significant amount of variation for each juvenile salmonid species.

EFFORTS OF TAYLOR SHELLFISH COMPANY TO ALLEVIATE THE PROBLEMS OF BURROWING SHRIMP ON AQUACULTURE GROUND IN WILLAPA BAY, WASHINGTON. Kurt Johnson, Taylor Shellfish Company, Shelton, WA 98584.

Oyster growers in Willapa Bay must find alternatives to controlling burrowing shrimp pests by spraying the insecticide Carbaryl. As part of this effort, Taylor Shellfish is testing several ideas. The approach is to find an alternate method to eradicate shrimp and/or work around the shrimp. A water jet sled was built as an alternate method to eradicate shrimp from the oyster beds. An array of water nozzles is mounted on a sled that is towed over the ground by an oyster boat. A high volume of water at up to 150 PSI is directed into the substrate to kill shrimp or expose them to predators. The design is still in progress, but preliminary results of testing are encouraging. We are testing an alternative growing method for the ability to disrupt newly settled shrimp. By using large seed on cultch or single oyster seed, the ground can be dredged more frequently. We will test for the effect of frequent dredging to inhibit shrimp recruitment. Growing single oysters is another option. Single oyster production increases the dollar yield per acre. Less acreage is required, and more money per acre can be spent on shrimp reduction. We are testing kumamoto, *Crassostrea sikamea*, and eastern oysters, *C. virginica*, in addition to Pacific oysters, *C. gigas*, for their higher dollar value. We are considering off-bottom culture for these valuable species.

GROWTH OF CULTURED GEODUCKS, *PANOPE ABRUPTA*, AT THREE INTERTIDAL SITES IN PUGET SOUND, WASHINGTON. Kurt Johnson, Taylor Shellfish Company, Shelton, WA 98584; Dan Cheney and Andrew Suhrbier, Pacific Shellfish Institute, Olympia, WA 98501.

Geoduck year classes from one to six years old were sampled over one to three years at three intertidal geoduck farms in Puget Sound Washington. Clams were measured for shell length and wet weight. At age three years and greater, one site showed significantly greater growth than the other two. Differences among the sites are discussed including current, food supply, density of clams, and substrate type. The effect of geoduck density on growth was investigated in three- and four-year-old geoducks. Density was measured on a scale of several square meters. At the two sites with lower growth, a regression of size to density showed smaller clams at the higher densities. Evaluation of the density effect will allow growers to adjust their planting densities for optimum growth. While substrate type was not quantified in this study, our observations indicate that substrate is very significant in determining geoduck growth rates.

Geoducks can be considered to be planted too densely in areas where geoduck density slowed growth. Using the biomass per square meter for clams close to harvest size in dense areas, we can estimate the carrying capacity for farm production purposes. This

number can be converted to a planting density to obtain the target harvest size clam within the desired time period.

DETECTION AND PRELIMINARY EVALUATION OF PARASITIC NATURAL ENEMIES FOR CONTROL OF BURROWING THALASSINID SHRIMP. Armand Kuris, M. Torchin, E. Ashley, S. Heerhartz, Department of Ecology, Evolution and Marine Biology, University of California, Santa Barbara, CA 93106; and B. Dumbauld, Washington State Department of Fish and Wildlife, Willapa Bay Field Station, Ocean Park, WA 98640.

An assessment of the presence and prevalence of native natural parasitic enemies of two species of burrowing thalassinid shrimp was conducted to determine whether there was any potential for augmentative biologic control. The shrimp cause significant problems for oyster aquaculture in West Coast estuaries by undermining the substrate that oysters grow on. Results were compared with a similar survey on ghost shrimp from southern California and northern Baja California. Ghost shrimp from Willapa Bay and Grays Harbor, Washington, were infected with two species of larval nematodes that are trophically transmitted, probably via teleost fish, whereas ghost shrimp from California were parasitized by trematode metacercariae and larval tapeworms (not found in Washington). Mud shrimp from Washington estuaries were heavily infected with a bopyrid isopod in the gill chamber. Prevalence was extremely high (>85%) at some locations and data collected at one site during the last 8 y suggests that prevalence has increased markedly over time while the population of shrimp has declined over the same period. Though no causal relationship can be established from this data alone, there is clearly some potential and further research is warranted.

NEXT STEPS FOR THE MOLLUSCAN BROODSTOCK PROGRAM: IMPROVING PACIFIC OYSTER BROODSTOCK FOR THE WEST COAST INDUSTRY. Chris Langdon, Sean Matson, John Brake, Drew Mosher, Ford Evans and David Stick, Coastal Oregon Marine Experiment Station and Department of Fisheries and Wildlife, Oregon State University, Newport, OR 97365.

The Molluscan Broodstock Program (MBP) was established in 1995 to improve yields of Pacific oysters on the West Coast of the United States through family-based selection. Yields of F_1 families derived from selected P_1 families were 9.5% greater than those of nonselected control families. "Generalist" families were identified that consistently performed well across a range of different grow-out sites. Shell shape as well as shell and mantle pigmentation are, in part, genetically determined, and these traits could be enhanced to improve product value in "boutique" markets. Commercial hatcheries are now using MBP broodstock for large-scale production. There is a need to develop a commercial repository to ensure

adequate future supplies of broodstock for the West Coast industry.

BETWEEN A ROCK AND A HARD PLACE: THE ECOLOGY OF OVIGEROUS GREEN CRAB, *CARCINUS MAENAS* (L.), WITH EMPHASIS ON IMPLICATIONS FOR MONITORING AND CONTROL EFFORTS. P. Sean McDonald, G. C. Jensen, and D. A. Armstrong, School of Aquatic and Fishery Sciences, University of Washington, Seattle, WA 98195.

Efforts to eradicate nonindigenous species or control their spread may fail if management plans do not specifically focus on critical or susceptible life history stages of the target organism. The case of European green crab, *Carcinus maenas*, in the northeastern Pacific provides one such example. Control strategies often rely on baited traps that primarily capture male crabs because ovigerous (egg-bearing) females are less mobile and unresponsive to bait. Yet removing males is of little consequence in limiting populations; one male can mate with multiple females within a season, and sperm storage by the latter may allow them to fertilize many broods from a single encounter. The targeted removal of ovigerous *C. maenas* may be an effective method for reducing propagule pressure, but the lack of information regarding their habitat use and behavior has hindered efforts. We conducted intertidal surveys in Tomales Bay, California, in May/June 2001, and experiments were undertaken at Bodega Marine Laboratory, Bodega Bay, California, to investigate substrate preference and habitat competition with native brown rock crab, *Cancer antennarius*. Survey observations suggest that aggregations of ovigerous *C. maenas* occur under boulders or other structure at +0.11 to +0.41 m MLLW. These crabs also preferentially bury in medium/coarse sand under field and laboratory conditions. Results of a competition experiment and nighttime video observations indicate that *C. antennarius* may affect the distribution and habitat use of ovigerous *C. maenas* in some areas. Implications for monitoring and control efforts are discussed as well as recommendations for future work.

ENVIRONMENTAL CONDITIONS AND EXPERIMENTAL INFECTION WITH *PERKINSUS MARINUS* MODULATE CELLULAR DEFENSE MECHANISMS IN THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*. Michael Goedken and Sylvain Deguise, Department of Pathobiology and Veterinary Science, University of Connecticut, Storrs, CT 06269.

The fast-growing oyster aquaculture industry is greatly hindered by the parasite *Perkinsus marinus*. The relationship between *P. marinus*, oyster defense mechanisms, and their environment is unclear. Apoptosis of Eastern oyster (*Crassostrea virginica*) hemocyte subpopulations was quantified at the single-cell level using flow cytometric Annexin-V and TUNEL assays. The influence of salinity (540 mOsm and 910 mOsm) and temperature

(14.50°C and >21.50°C) were evaluated experimentally on both the host and the parasite. The *in vivo* and *in vitro* effects of *P. marinus* infection on oyster hemocytes were measured as well. Forward and side scatter distinguished two populations of hemocytes (granulocytes, hyalinocytes) with previously demonstrated unique functional characteristics. Controlled environment and infection studies revealed significant defense mechanism alterations. Apoptosis was always higher in granulocytes than hyalinocytes regardless of temperature or salinity. Salinity affected apoptosis of both subpopulations with increased apoptosis at high as compared with low salinity irrespective of temperature. Parasite apoptosis was significantly higher at low salinity. *In vivo P. marinus* infection of oysters did not significantly affect hemocyte apoptosis, though *in vitro* infection resulted in greater apoptosis in infected granulocytes. We demonstrated that water salinity and experimental infection with *P. marinus* but not water temperature modulated oyster defense mechanisms. A better understanding of how these variables affect oysters defense mechanisms may lead to management strategies that will result in reduced disease morbidity and mortality for oyster producers.

ANALYSIS OF LARVAL AND JUVENILE PERFORMANCE IN CROSSBRED LINES OF PACIFIC OYSTERS, *CRASSOSTREA GIGAS*, UNDER THREE FEEDING REGIMES. Lizzie Nelson, Carolyn Friedman, School of Aquatic and Fishery Sciences, University of Washington, Seattle, WA 98195; Jonathan Davis, Taylor Resources, Inc., Quilcene, WA 98376; and Dennis Hedgecock, Department of Biologic Sciences, University of Southern California, Los Angeles, CA 90089.

Pacific oysters exhibit heterosis, the positive effect of heterozygosity seen in hybrid families. The goals of this study were to determine if rank of hybrid and inbred families varies as a function of food level, to examine within-family variation in growth and survival, and to investigate the relationship between larval and juvenile growth. Three inbred and six hybrid genotypes were replicated either in three food levels or by using three parent pairs per cross. Live wet weights and counts were taken throughout the experiment. Mortality, shell area of larvae (μm^2), and specific growth rate (SGR) will be analyzed. Rank of hybrid and inbred families' SGRs did not vary as a function of food level ($P = 0.006$) from days 39–67 postfertilization. Results after growout in Thorndyke Bay, Washington, are presented with an examination of the role of larval performance in adult yield prediction.

TRIALS OF ALTERNATIVE CHEMICAL AND MECHANICAL TACTICS TO MANAGE BURROWING SHRIMP—

2003 Kim Patten, Wsu Long Beach Res & Ext. Unit, Long Beach, WA 98631; **James Durfey**, Department of Biomechanical Engineering, Pullman, WA 99164; and **Steven Booth**, Willapa Bay-Grays Harbor Oyster Growers Association, Nahcotta, WA 98637.

Summer 2003 was the second experimental season to feature a series of randomized block designs using small field plot (2 × 2 m) to compare EPA 25-B list ("easily registered") compounds, bio-rational compounds, adjuvants, and reduced rates of the conventional burrowing shrimp compound, carbaryl (Sevin @ 8 lb a.i./ac, Bayer Corp.). Experimental materials were applied using a CO₂ backpack sprayer. A separate larger strip-plot (2 × 6 m) trial featured additional treatments of subsurface injection and postapplication rolling or harrowing. In all trials, shrimp burrows per m² were counted periodically after treatment and were compared using ANOVA. None of the unconventional treatments reduced burrow densities below the generally accepted threshold for oyster production of 10 per m. In an initial trial, burrow density was significantly lower in plots treated topically with acetamiprid (Assail @ 4.7 oz a.i./ac) compared with either carbaryl (2 lb a.i./ac) or the untreated check. These results contrast with those of the larger strip plot trial, however, where shrimp burrow densities were lower in carbaryl-treated plots (3 lb a.i./ac) than in acetamiprid-treated plots (14.4 oz a.i./ac). Burrow densities were initially lower in plots treated topically compared with injection, but differences were not significant at 4 wk after application. Effects from post-application rolling did not differ significantly from those due to postapplication harrowing.

METHODOLOGY OF DUNGENESS CRAB ASSESSMENT IN BRITISH COLUMBIA. Antan Phillips

, Fisheries and Oceans Canada, Pacific Biologic Station, Nanaimo, BC, Canada V9T 6N7.

Dungeness crab (*Cancer magister*) stocks on the Pacific coast have been sustained for well over one hundred years through minimum harvest size regulation alone. Assessment activities are therefore not directed at establishing harvest quotas but at improving fishery viability and providing access to the resource for all stakeholders. Assessments vary with information requirements and incorporate a variety of information sources including harvest logs, sales slips, and commercial sampling in addition to directed survey data. Assessment methodologies are described as they are applied to specific investigations and data requirements. Biological assessment focuses on analysis of trap-caught crabs either from commercial fisheries or from directed surveys conducted by Fisheries & Oceans Canada using standardized gear. Detailed information regarding harvest parameters as well as biological information on individual crabs is collected according to a standard format. A protocol for the collection of biologic information on crabs and the logistics of field data collection are presented.

WASHINGTON DEPARTMENT OF FISH AND WILDLIFE SHELLFISH DISEASE, PEST, AND PREDATOR CONTROL PROGRAM. Russell E. Rogers, Jr.

Washington State Department of Fish and Wildlife, Point Whitney Shellfish Laboratory, Brinnon, WA 98320.

The Washington Department of Fish and Wildlife (WDFW) controls the introduction of new shellfish diseases, pests, and predators through the issuance of Shellfish Import Permits. The spread of diseases, pests, and predators already established in the state are controlled by the issuance of Oyster and Shellfish Transfer Permits. Recent changes in the status of established diseases, pests, and predators (Denman Island Disease [DID], Japanese oyster drill, and European green crab) has warranted some new restrictions on the intrastate transfer of shellfish. Following the discovery of DID, in Dungeness Bay, Clallam County, Washington, in May 2002, WDFW quickly established a surveillance program to monitor the disease. Samples were gathered from 18 sites in 2002 and 2003. At least seven additional sites (Westcott Bay, Deer Harbor, East Sound, and West Sound [all in San Juan County], Bellingham Bay, Samish Bay, and McMicken Island State Park) have been identified as positive for the disease. Data collected from the DID surveillance program has been used to establish DID prohibited and DID surveillance. Transfers within the surveillance areas will now require a written permit from WDFW. Surveys for Japanese oyster drills have identified five new infested areas (Duckabush river mouth, Jorsted Creek, the hook of the Hood Canal, Vaughn Bay, and Minterbrook Creek). These areas are now considered drill-restricted areas. Due to budgetary constraints, the European Green Crab Control Program was cut at the end of June 2003. The Puget Sound volunteer monitoring effort may continue if alternative funding can be secured.

ASSESSMENT AND MANAGEMENT OF SPOT PRAWN, *PANDALUS PLATYCEROS*, ALONG THE BRITISH COLUMBIA COAST. Dennis T. Rutherford, H. Nguyen, J. Boutillier

, Fisheries and Oceans Canada, Pacific Biologic Station, Nanaimo, BC, Canada V9T 6N7; and **J. Morrison**, Fisheries and Oceans Canada, Nanaimo, BC, Canada V9T 1K3.

Prawns, *Pandalus platyceros*, are the largest of the seven species of shrimp harvested along the coast of British Columbia. The commercial trap fishery accounts for more than 95% of the total prawn landings and represents the most valuable shrimp fishery in British Columbia. Landed values during the past few years have been in excess of \$25M Cdn. The prawn by trap fishery is managed by Fisheries and Oceans Canada to prevent both growth and recruitment overfishing. Growth overfishing is controlled through a combination of seasonal closures, size limits, trap mesh size requirements, fishing time restrictions, and a single haul limit. Recruitment overfishing is controlled using a fixed escapement-based model. Escapement is indexed based on the number of female spawners per trap. Implementation of the fixed escapement

strategy is carried out through an in-season, industry-funded monitoring program. The assessment and management frameworks for prawns appear to have been fairly successful; nevertheless, the fixed escapement model still requires improvements to achieve optimum production from all areas of the coast.

USING GIS TO ENHANCE UNDERSTANDING OF SPATIAL AND TEMPORAL INTERTIDAL CLAM DISTRIBUTION PATTERNS IN NORTH PUGET SOUND. Catherine A. Stanley and Bridget C. Gregg, Washington Department of Fish and Wildlife, Region 4 Shellfish, Mill Creek, WA 98012.

Geographic Information Systems (GIS) mapping technologies can be used to enhance spatial and temporal understanding of biologic systems. During annual clam population surveys, Washington Department of Fish and Wildlife (WDFW) shellfish biologists set transect lines at 100-foot intervals across the clam-band of a beach and collect 1-ft.³ samples at regular 40-ft. intervals along each transect line. Data recorded includes the GPS waypoints, species, number, length, and weight of clams and substrate type for each sample. This year, a pilot project was implemented to import these data into a GIS database using ArcView 3.2. Resource maps were created for several of the most popular beaches in North Puget Sound, mapping the distribution of *Protothaca staminea*, *Venerupis philippinarum*, and *Saxidomus giganteus*. GIS facilitated post-survey stratification of clam species by tidal elevation and substrate strata. Subsequent statistical analysis that incorporated these strata demonstrated local habitat preferences of recreationally targeted clams.

CONCERN OF DECREASED RESPONSE WHEN ADDING CANDIDATE GENE INFORMATION TO SELECTION INDEX CONTAINING PHENOTYPIC DATA. David A. Stick, Department of Fisheries and Wildlife, Oregon State University, Hatfield Marine Science Center, Newport, OR 97365.

Technological advancements have made possible direct genotypic selection for quantitative traits. It has been postulated that incorporation of genetic information in a phenotypic-based selection scheme will increase genetic response (ΔG) as result of increased selection accuracy and decreased generation interval. A Monte-Carlo gene-level simulation program was created to mimic meiotic events and test this hypothesis. Three levels of heritability (h^2) were investigated: very low (0.01), low (0.1), and moderate (0.4), together with three selection schemes: phenotypic (P_C), genotypic (G_C), and a combination (C_{PG}) index of both information sources. Response to selection only benefited from incorporation of genotypic information when heritability was very low ($C_{PG} > P_C > G_C$). Selection based solely on phenotype demonstrated the greatest response when heritability was low or moderate ($P_C > C_{PG}$

$> G_C$). Across all heritabilities, favorable polygenic frequency increased more with phenotypic selection ($P_C > C_{PG} > G_C$), whereas both the number of favorable alleles lost due to random genetic drift and the rate of inbreeding were greatest with genotypic selection ($G_C > C_{PG} > P_C$). Index optimization significantly reduced the difference in predicted response between phenotypic and combined selection approaches, but general trends remained. Results demonstrate that placing too much emphasis on selection of candidate genes can be detrimental to breeding programs. However, incorporation of genetic information in optimized selection programs may help minimize loss of favorable alleles.

CAN OYSTERS AND EELGRASS CO-EXIST? INTERACTIONS BETWEEN *CRASSOSTREA GIGAS* AND *ZOSTERA MARINA* OUTSIDE AN AQUACULTURE SETTING. Heather M. Tallis, J. L. Ruesink, Biology Department, University of Washington, Seattle, WA 98195-1800; Lorena M. Wisehart, S. D. Hacker, School of Biologic Sciences, Washington State University Vancouver, Vancouver, WA 98686; and Brett R. Dumbauld, Washington State Department of Fish and Wildlife, Willapa Bay Field Station, Ocean Park, WA 98640.

Recent surveys of eelgrass (*Zostera marina*) in oyster (*Crassostrea gigas*) aquaculture areas have shown that aquaculture can decrease eelgrass density in Willapa Bay, Washington. Identifying which of the many aspects of oyster aquaculture is responsible for low eelgrass density is crucial to the advancement of sustainable culture practices. We conducted two types of oyster density manipulations in Willapa Bay during the past two years to assess the effects of oysters on eelgrass separate from other aspects of aquaculture, like disturbance during planting and harvest. Early results showed no significant relationship between oyster density and eelgrass growth. However, because some current aquaculture practices leave oysters on beds for multiple years, it is important to understand the long-term effects of oysters on eelgrass. We will discuss seasonal variation in eelgrass growth related to adult oyster density and annual variation in eelgrass growth related to spat density. Pore water nutrient levels were also measured to distinguish physical effects of oyster shell from biological effects of oyster waste production. These results will be related to eelgrass growth.

ASSESSMENT AND MANAGEMENT OF INTERTIDAL CLAM RESOURCES IN NORTHERN PUGET SOUND. Jennifer Whitney and Darcy Wildermuth, Washington Department of Fish and Wildlife, Region 4, Mill Creek Office, Mill Creek, WA 98012.

Puget Sound has a mix of publicly and privately owned tidelands, a complex situation for resource management. Since the

court order of United States District Court Judge Rafeedie in 1994 honoring treaties signed by Governor Stevens and Puget Sound tribes in 1854–1855, tribal governments and the Washington Department of Fish and Wildlife (WDFW) have co-managed intertidal shellfish on the more than 1300 public beaches in Puget Sound. Tribal harvesters, both commercial and subsistence, and non-tribal recreational harvesters split the allowable harvest 50:50. Public beaches are individually managed to provide both harvest opportunity and population stability for Manila and Native Little-neck clams, the primary species targeted by recreational harvesters. The Tribes and the WDFW follow an established random transect survey protocol to estimate clam populations. The total allowable catch (TAC) is set at 33% of Manilas >38 mm and 25% of Natives >38 mm. WDFW sets seasons and bag limits to keep recreational harvest at or below the recreational share of the TAC. Recreational effort is monitored by aerial surveys that count harvesters within a one-hour window of low tide on a series of public beaches. Counts for individual beaches are expanded by a factor derived from on-the-ground ingress observations over the six-hour low-tide period. Recreational catch is estimated by conducting creel surveys as harvesters egress the beach. Effort and catch estimates are combined to yield an estimate of total annual recreational harvest for each beach. If 50% of the TAC for a beach is exceeded by recreational harvest, the overage is accounted for by shortening the season or closure the following year. Though recreational harvest estimation methods have been in place for more than 15 y, technological advances such as GIS are increasing the precision of our estimates.

THE EFFECTS OF DIFFERENT AQUACULTURE TECHNIQUES ON *ZOSTERA MARINA* BIOMASS, DENSITY, AND GROWTH RATES IN WILLAPA BAY, WASHINGTON. Lorena M. Wischart, S. D. Hacker, School of Biologic Sciences, Washington State University Vancouver, Vancouver, WA 98686; Heather M. Tallis, J. L. Ruesink, F. Oyarzun, Biology Department, University Of Washington, Seattle, WA 98195-1800; and Brett R. Dumbauld, Washington State Department of Fish and Wildlife, Willapa Bay Field Station, Ocean Park, WA 98640.

Influence of shellfish aquaculture on eelgrass has been understudied in Pacific Northwest estuaries. In an effort to quantify possible positive and negative effects of shellfish aquaculture, we investigated the relationship between oyster culture type and eelgrass at three sites in Willapa Bay, Washington. At each site, we sampled an off-bottom long-line culture area, a dredged ground culture area, a handpicked ground culture area, and an area without aquaculture. We measured the standing biomass, percent cover and growth rate of eelgrass, as well as the density of vegetative and flowering shoots. In general, we found the largest growth rates in areas with off-bottom culture and those without aquaculture; these areas also had the greatest eelgrass biomass, density, and percent cover. Eelgrass growth and biomass were lower in handpicked and dredged culture areas and did not significantly differ from one another. Interestingly, there were significant site and culture type interactions for most variables suggesting that site-specific conditions may be as influential as culture technique in determining eelgrass growth.

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans*, or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual*, distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").

- Figures must not be embedded in a word-processor or spreadsheet document; the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.

- Resolution: *line shots*: 1000 dpi; *halftones/grayscale*: 300 dpi if no lettering, 500 dpi if figure contains lettering.

- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements as B/W, above.

Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations*, available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

Page Charges: Authors or their institutions will be charged \$100.00 per printed page. All page charges are subject to change without notice. A handling fee of \$50 will be charged for all manuscripts accepted for publication.

Proofs: Page proofs are sent to the corresponding author and must be corrected and returned within seven days. Alterations other than corrections of printer's errors may be charged to the author(s).

Reprints: Reprints of published papers are available at cost to the authors. Information regarding ordering reprints will be available from The Sheridan Press at the time of printing.

Cover Photographs: Appropriate photographs may be submitted for consideration for use on the cover of the *Journal of Shellfish Research*. Black and white photographs and color illustrations will be considered.

Corresponding: An original and two copies and electronic copy of each manuscript submitted for publication consideration should be sent to the Editor, Dr. Sandra E. Shumway, Department of Marine Sciences, University of Connecticut, 1080 Shennecossett Rd., Groton, CT 06340. E-mail: sandra.shumway@uconn.edu or sandrashumway@hotmail.com

Membership information may be obtained from the Editor or the Treasurer using the form in the *Journal*. Institutional subscribers should send requests to: *Journal of Shellfish Research*, P.O. Box 465, Hanover, PA 17331.

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations; the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

- Sponsors an annual scientific conference.
- Publishes the peer-reviewed *Journal of Shellfish Research*.
- Produces a Quarterly Newsletter.
- Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

- You will meet kindred scientists, managers and industry officials at annual meetings.
- You will get peer review through presentation of papers at the annual meeting.
- If you are young, you will benefit from the experience of your elders.
- If you are an elder, you will be rejuvenated by the fresh ideas of youth.
- If you are a student, you will make useful contacts for your job search.
- If you are a potential employer, you will meet promising young people.
- You will receive a scientific journal containing important research articles.
- You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

- Fill out and mail a copy of the application blank below. The dues are 65 US \$ per year (\$35 for students) and that includes the *Journal* and the Newsletter!

NATIONAL SHELLFISHERIES ASSOCIATION—APPLICATION FOR MEMBERSHIP (NEW MEMBERS ONLY)

POPULATION BIOLOGY OF THE PACIFIC GEODUCK CLAM, *PANOPEA ABRUPTA*, IN EXPERIMENTAL PLOTS, SOUTHERN BRITISH COLUMBIA, CANADA

A. CAMPBELL,¹ C. W. YEUNG,¹ G. DOVEY² AND Z. ZHANG¹

¹Pacific Biological Station, Nanaimo, BC, Canada V9T 6N7; ²West 123° Resource Consulting Inc., PO Box 781, Ladysmith, BC, Canada V9G 1A6

ABSTRACT Information was presented on the density, recruitment to harvestable size, and growth of the Pacific geoduck clam, *P. abrupta*, in 0.25 ha experimental plots with controlled fishing in two areas of southern British Columbia over a 9-year period. In two plots that had high exploitation in the first 3 years, the geoduck population densities and the average age (by removing old individuals) were substantially reduced, but thereafter densities slowly increased due to geoduck recruitment. Recruitment was similar between plots after high and low exploitation rates, suggesting that fishing and different geoduck densities had no long term effect on subsequent recruitment. After removing many old individuals from a geoduck population, the mean maximum asymptotic length (L_{∞}) of the von Bertalanffy growth model decreased, and the Brody growth function k values increased. In plots where there was low exploitation and geoduck densities remained similar over time, L_{∞} values also remained similar, but k values varied with time suggesting other biologic or environmental factors could have influenced growth rates.

KEY WORDS: geoduck, *Panopea abrupta*, density, recruitment, growth

INTRODUCTION

The Pacific geoduck clam, *Panopea abrupta* (Conrad, 1849), is a large hiatellid bivalve found buried up to 1 m within mud and sand substrates. This geoduck species is distributed in coastal areas from the intertidal zone to at least 100 m (Jamison et al. 1984) from California to Alaska and to southern Japan (Coan et al. 2000). Commercial fisheries occur for *P. abrupta* in Washington State, British Columbia and Alaska (Campbell et al. 1998a, Bradbury & Tagart 2000, Hand & Bureau 2000) with annual landed values varying between 32 and 42 million Canadian dollars in British Columbia during 2000 to 2003. Adult geoduck generally have separate sexes and broadcast spawn usually during summer (Andersen 1971, Sloan & Robinson 1984, Campbell & Ming 2003). Planktonic larvae remain in the water column 16 to 47 days, settle as postlarvae on substrates, and subsequently burrow into suitable substrates (King 1986, Goodwin & Pease 1989). Geoduck juveniles and adults feed by filtering food particles (e.g., phytoplankton) from seawater (Goodwin & Pease 1989). Geoduck growth is variable, depending on a variety of environmental factors, but fastest during their first 10 y (Goodwin & Shaul 1984, Goodwin & Pease 1991, Harbo et al. 1983, Bureau et al. 2002, Noakes & Campbell 1992, Hoffmann et al. 2000). Geoduck are long-lived, reaching ages of up to 168 y (Bureau et al. 2002). Geoduck recruitment was considered to be variable but low (Breen & Shields 1983, Harbo et al. 1983), however recent studies of age frequencies have suggested strong recruitment events to adult geoduck populations throughout BC since 1988 (Bureau et al. 2002, Bureau et al. 2003). Natural mortality rate (M) estimates of adult geoduck in British Columbia range from 0.01–0.04 (Breen & Shields 1983, Harbo et al. 1983, Noakes 1992).

Little is known of the effects of fishing on the population biology of *P. abrupta* (e.g., Goodwin 1978, Campbell et al. 1998a). The objective of the study was to investigate the effects of fishing on geoduck population biology. The purpose of this study is to present information on the density, recruitment to harvestable size, and growth of *P. abrupta* in small experimental plots with controlled fishing in two areas of southern British Columbia over a 9-year period. Further analyses of geoduck recruitment and natural mortality of this study are presented in Zhang and Campbell (2004).

Experimental Plots

The study areas were located at Ritchie Bay (northwest Meares Island on the west coast of Vancouver Island) and southwest Marina Island (Georgia Strait) of British Columbia. Ritchie Bay has been closed to commercial fishing and designated as a research reserve since 1980, when Fyfe (1984) started his geoduck study. The area around Marina Island was heavily harvested during 1978–1989 and was subsequently closed to commercial fishing for geoduck since 1990 (Campbell et al. 1996b). For this study, 4 experimental plots were established at Ritchie Bay [(1) 125°55.242'W, 49°13.502'N; (2) 125°55.179'W, 49°13.506'N; (3) 125°55.076'W, 49°13.488'N; (4) 125°55.046'W, 49°13.549'N] during 1991 and 3 plots established at Marina Island [(1) 125°03.734'W, 50°03.001'N; (2) 125°03.745'W, 50°02.959'N; (3) 125°03.826'W, 50°02.955'N] during 1992.

Each experimental plot comprising a 0.25 ha area (50 × 50 m), was delineated and subdivided into 10-m sections with lead lines to provide five 500 m² strips (50 × 10 m). Experimental plots 1, 2, and 3 at Ritchie Bay were slightly smaller (0.244 ha) than the other plots because 0.006 ha/plot were reserved for potential show factor plots (see later). The minimum-maximum depth (m) at datum for each experimental plot at Ritchie Bay was (1) 7.8–11.8; (2) 10.0–10.9; (3) 7.7–9.8; and (4) 10.7–11.6 and at Marina Island (1) 11.7–14.5; (2) 11.6–15.4; and (3) 12.2–16.8. The bottom substrates comprised of soft mud to fine sand and shell mixture at Ritchie Bay and fine sand with some small gravel at Marina Island.

Experimental Treatments

The chronology of events for each plot and year included an abundance (show factor and density) survey, biosample, and or commercial harvest (Table 1). Each plot was randomly chosen for a different treatment in terms of a depletion harvest regimen (Table 1, 2). The general harvest regimen in each plot for Ritchie Bay was (1) moderate, (2) none, (3) heavy, and (4) none, and for Marina Island was (1) none, (2) moderate, and (3) heavy. In an attempt to determine if seeding of hatchery-raised juvenile geoduck could supplement natural recruitment. Plot 1 and Plot 2 of Ritchie Bay,

were artificially seeded at approximately 16 m^{-2} with younger then 0.5-y-old hatchery-raised juvenile geoduck of mean 11.3 mm shell length (SL) (min. 6 mm SL, max. 18.4 mm SL, $n = 136$) during September 1991. Plot 4 of Ritchie Bay and Plot 1 of Marina Island were considered the control treatment as the only removals made were for biosamples and were not seeded with hatchery-raised juvenile geoduck. No treatment was replicated with addi-

tional plots in the same study area because of the considerable logistical costs involved.

Densities

Geoduck density was estimated using survey methods described by Campbell et al. (1996 a, 1996 b). The survey method for

Plots 1, 2, and 3 from Ritchie Bay were 0.244 ha/plot, the rest were 0.250 ha/plot. Removed total and density includes the harvest and biosample removals. no, number; CI, confidence interval.

each plot involved counting geoduck siphons in 5-m² (5 × 1 m) quadrats along ten 50-m one meter wide transects. Two transects were placed on either side of the four inner subdivision boundaries and one transect each was placed on the two inner sides of the study area border for a total of 10 transects per plot. Six of the eight inner transects for Plots 1, 2, and 3 in Ritchie Bay were shortened because they had 10 m reserved as potential show factor plots, where no geoduck was removed. Consequently, 10 m² for each of these 6 transects per Plot 1, 2, and 3 were not used in the density estimates for Ritchie Bay. The total area considered for geoduck density surveys and harvest was 2440 m² for Ritchie Bay Plots 1, 2, and 3 and 2500 m² for Ritchie Bay Plot 4 and all three plots of Marina Island. There were 88 quadrats surveyed for Ritchie Bay Plots 1, 2, and 3 and 100 quadrats surveyed for Ritchie Bay plot 4 and Marina Island Plots 1, 2, and 3 for each density survey.

Survey dates for geoduck densities at Ritchie Bay were July 25 to August 14 1991; May 13–27, 1992; May 17–19, 1993; May 17–19, 1995; May 31 to June 1, 1996; May 24–25, 1997; July 9–10, 2000; and at Marina Island were July 15, 1992; July 8–9, 1993; June 6, 1994; June 4–5, 1996; September 18–19, 1997; October 5, 1999; September 7–8, 2001 (Table 1).

Show Factor

Because all geoduck may not show their siphons at the substrate surface at any one time, "show" plots were used to determine the percentage of exposed geoduck (i.e., showing their siphons each day). In Ritchie Bay, only the three show plots in Plot 2 were used throughout this study. In the Marina Island study area, the three show plots were placed 5–10 m outside the borders of the three experimental plots. Each 20 m² show plot (i.e., 2 × 10 m, subdivided into four 1 × 5 m quadrats) was marked with lead line providing a total of 12 quadrats in the three show plots of each study area. Each geoduck showing in the show plots was marked beside the neck with a "flag" (stainless steel wire) in the substrate. The proportion of geoduck showing (the show factor) on any given day was determined by dividing the number showing on that day by the cumulative total number of geoduck flagged during the period that the show plots were monitored each year. Monitoring of the show plots started several days before the density surveys were conducted in the experimental plots. Sometimes not all the show plots were monitored. On a few occasions, less than three show plots were surveyed, and the available data were used for the analyses.

For most plots, both the shows and density were surveyed on the same day. However, for a few days some Ritchie Bay plots did not have show factor and density surveys on the same day, in which case the show factor used was interpolated (averaged) between dates. One exception to a reliable interpolation occurred for the geoduck density estimate at Ritchie Bay Plot 1 which was surveyed during August 7–14, 1991 when the show factor had been measured on July 26 and 31 and August 1 and 15, 1991 and estimated to be 0.96. This show factor value was clearly incorrect and too high because of a severe storm, with 115.6 mm of rain and south east winds of up to 43 km/hour, occurred on August 7, 1991 (Environment Canada web site for Tofino Airport [125°24'W, 49°4'N] http://www.climate.weatheroffice.ec.gc.ca/climateData/canada_e.html). The diver surveying for geoduck density on the August 15, 1991 also recorded that geoduck were not showing well due to a "winter like storm" the previous week. Campbell et al.

(1996a) found that show factor decreased to about 0.65 following a strong storm near Comox during June 1993. All measured show factors at Ritchie Bay were higher than 0.80. Show factor data from the Marina study area on July 8, 1993 also provided a reduced show factor of about 0.66, due to increased wind speeds (hourly weather and wind speeds and direction were examined for Campbell River Airport [125°16'W, 49°57'N; see website: http://www.climate.weatheroffice.ec.gc.ca/climateData/canada_e.html] a location near to Marina Island, during the survey periods and about 5 days prior to the survey). Consequently a show factor value of 0.66 was considered reasonable to be used in the density calculations for Ritchie Bay Plot 1 in 1991.

Removals

Geoduck were removed from each plot for two reasons: (1) to deplete the population through commercial harvest, and (2) to collect a biosample for aging. Removal of geoduck from each plot was always conducted soon after the density surveys had been completed. An experienced fisherman used the usual commercial harvest methods (Campbell et al. 1998a) to systematically harvest each of the five strips per plot right up to the rope borders on each day fished. This ensured, as much as possible (except for environmental influences such as tidal current and visibility variation), that all geoduck had an equal chance of being harvested in the plot on each day during the study. A target number for each biosample was a minimum of approximately 500 geoduck per plot (i.e., 100 per strip). Biosamples with 50 less than the 500 geoduck target were probably due to the divers not being able to find the extra individuals at low geoduck densities in the plots. When more than 1000 geoduck were removed per plot, the first approximately 500–600 geoduck were used as a biosample. Geoduck within the potential three 20 m² show factor plots in each of the Ritchie Bay Plots 1, 2, and 3, however, were not removed, making the actual area harvested 2440 m² per plot. The total number of geoduck removed per plot per year is shown in Table 2.

Biosamples

For each geoduck, the shell length (SL) was measured as the straight-line distance between the anterior and posterior margins of the shell to the nearest mm with veneer calipers. The age of each geoduck was estimated using the acetate peel method of Shaul and Goodwin (1982). One valve per geoduck was sectioned through the hinge plate, the cut surface polished, etched with a 1% hydrochloric acid solution for approximately 1 minute, washed with distilled water, dried, and an acetate peel made by applying first acetone, then an acetate sheet on the hinge surface. Annual growth rings imprinted on the acetate peel were counted on a digitizing table after ×40 magnification using a Neo-Promar projector. Shaul and Goodwin (1982) and Noakes and Campbell (1992) provide further details in shell preparation and age validation procedures. Although most individuals had both their SL and age measured, there were some that had only the SL or only the age measured; these latter individuals were included in the analysis only where appropriate.

To determine the weight of geoduck necks by age at recruitment, sub samples of between 45 and 115 geoduck, with as wide a size range as possible, were obtained from each biosample. For each geoduck, the neck was cut at the base from the body, cut longitudinally along the siphons to remove excess water and weighed in grams.

Data Analyses

Density

The mean show-adjusted density, D (number m^{-2}), for each plot was calculated as

$$D = \frac{\frac{1}{n} \sum_{i=1}^n d_i}{\frac{1}{m} \sum_{j=1}^m S_j} \quad (1)$$

where d_i is the density of geoduck (i.e., number of geoduck m^{-2} or number of geoduck per 1×5 m quadrat divided by 5) in the i^{th} quadrat, S_j is a proportion of geoduck showing in the j^{th} show quadrat, n is the total number of quadrats sampled to estimate geoduck density, and m is the total number of show quadrats (i.e., twelve 1×5 m quadrats) used for estimating show factor in each study area. Hereafter density in this study refers to show-adjusted density.

Distribution-free unbiased bootstrap techniques (Efron & Tibshirani 1993) with S-plus (2001) computer programs were used to estimate 95% confidence intervals (CI) for the mean show-adjusted density. Eq. 1 was used to obtain a new mean show-adjusted density by randomly resampling, with replacement, m new show factors from the original m show factors and n new density counts from the original n density counts. This procedure was repeated 1000 times. To produce the $(1-2\alpha)$ CI of show-adjusted density, the α percentile (2.5%) and the $1-\alpha$ percentile (97.5%) of the bias-corrected and accelerated (BCa) distribution of the 1000 show-adjusted densities were used as the lower and upper CI bound, respectively (Efron & Tibshirani 1993).

Exploitation

Exploitation was calculated as R/D , where R is the removed density (number of geoduck m^{-2} calculated as total number of geoduck divided by the plot area harvested), and D is the geoduck density (mean, 95% CI) surveyed just prior to removal.

Age Frequencies

The age frequency data were standardized for density to allow comparison of the number of geoduck m^{-2} belonging to a particular age group between plots and years. The equation used was:

$$D_a = p_a \times D \quad (2)$$

where D_a is the estimated mean density of geoduck of age a , p_a is the proportion of geoduck of age a (number of individuals of age a divided by total number of known age) in the bio-sample, and D is the mean show-adjusted density.

The 95% CI for density of age a were calculated using a bootstrap algorithm (Efron & Tibshirani 1993, S-plus 2001). Eq. 1 and 2 were used to obtain a new estimate by randomly resampling, with replacement, m new show factors from the original m show factors, n new density counts from the original n density counts, and k new age estimates from the original k age estimates. The m new show factors and the n new density count were used to estimate D , and the p_a was estimated by counting the number of age a in the k new age estimates. This procedure was repeated 1000 times. To produce the $(1-2\alpha)$ CI of show-adjusted density at age, the α percentile (2.5%) and the $1-\alpha$ percentile (97.5%) of the bias-corrected and accelerated (BCa) distribution of the 1000

show-adjusted densities were used as the lower and upper CI bound, respectively (Efron & Tibshirani 1993).

Pair-wise comparisons to test for differences in age frequencies between plots and years were conducted using the Mann-Whitney test.

The figures for age frequencies adjusted to density were truncated to 100 y for graphical purposes because there were few geoduck found older than 100 y in both study areas.

Recruitment

Recruitment was defined as the density of geoduck growing into the population that were fully vulnerable to fishing. We assumed recruitment to occur when all of the necks of geoduck of the youngest age cohort were large enough to be clearly seen by divers when showing at or above the substrate. The threshold criterion used for recruited geoduck neck size at the youngest age was where the lower 95% CI of the mean neck wet weight was equal to 100 g or higher. Recruitment for geoduck from the Ritchie Bay area was 6 y, (neck weight mean = 148.2, lower-upper 95% CI =

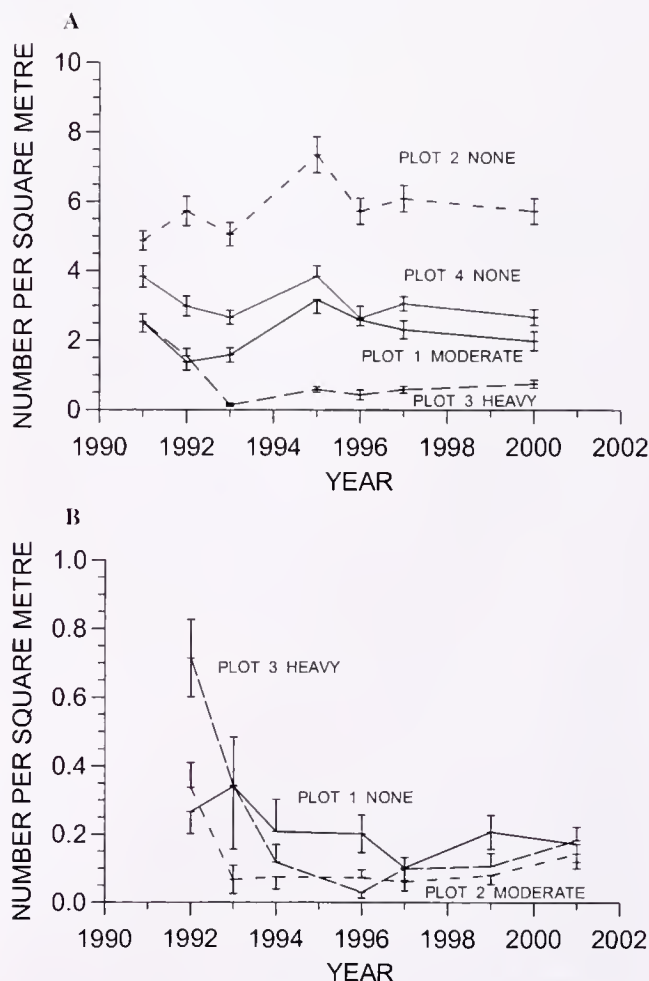

Figure 1. Density of geoduck in the study plots from (A) Ritchie Bay, 1991–2000, and (B) Marina Island, 1992–2001. Densities were adjusted for show factor. Vertical lines are upper and lower 95% CI; where there is an overlap of CI for two or more plots in a year only the upper or lower CI is shown for each plot. Harvest treatments were for Ritchie Bay plot (1) moderate, (2) none, (3) heavy, (4) none, and for Marina Bay plot (1) none, (2) moderate, (3) heavy.

130.5–165.9, $n = 34$), and from the Marina Island area was 7 y (neck weight mean = 124.2, lower-upper 95% CI = 104.2–144.2, $n = 22$). The densities of age 6 and 7-y geoduck and 95% CI for each plot were calculated as described in the previous section above. Because there were no replicates for each plot-treatment, for comparisons between plots and years, we considered overlapping 95% CI to suggest similarities in mean densities at age, and nonoverlapping 95% CI to suggest a difference in mean densities at age.

Growth

The relationship between shell length and age was estimated with the von Bertalanffy (1938) growth model

$$L_t = L_\infty[1 - e^{-k(t-t_0)}] + \varepsilon \quad (3)$$

where t is age in years, L_t is shell length (mm) at age t , L_∞ is the mean asymptotic length (mm), k is the Brody growth coefficient determining rate of increase or decrease in length increments, t_0 is

a phase-variable, suggesting the hypothetical age at which the organism would have been at zero length, and $\varepsilon \sim N(0, \sigma^2)$ is a normal variate. The parameters L_∞ , k , t_0 , and ε were estimated using maximum likelihood methods (Bain & Engelhardt 1991) in the statistics program of S-Plus (2001). Only undamaged geoduck shells were used for the growth analyses. Initial analyses indicated that t_0 values were either far too positively or negatively large in the biosamples that had few young geoduck. For consistency, we followed the same approach of Bureau et al. (2002) by setting t_0 as zero for all samples causing the fitted curves through the origin and re-estimating L_∞ , k , and ε .

The 95% CI for the parameters L_∞ , k , and ε from each biosample were calculated using a bootstrap algorithm as follows. Pairs of age length data for individual geoduck were randomly resampled, with replacement, from the original data up to the biosample size n , and then Eq. 3 (with $t_0 = 0$) was used to obtain estimates of the parameters. This procedure was repeated 1000 times. To produce the $(1-2\alpha)$ CI for each of L_∞ , k , and ε ; the α percentile (2.5%) and the $1-\alpha$ percentile (97.5%) of the bias-corrected and accelerated (BCa) distribution of the 1000 values of each parameter were used as the lower and upper CI bound, respectively (Efron & Tibshirani 1993).

Pair-wise comparisons for hypothesis testing of simultaneous differences in parameters L_∞ and k between all biosamples were conducted using the likelihood ratio test outlined by Kimura (1980) to determine if geoduck growth rates were different between plots and years.

Relation Between Density, Recruitment, and k

Regression analyses (using the least squares method) were used to determine if there were significant relationships between the Brody growth coefficient k and mean overall density or recruitment density, for each plot and year at Ritchie Bay.

TABLE 3.

Summary statistics of unmodified age data from the Ritchie Bay and Marina Island experimental plot biosample data.

		Age (years)					
Year	Plot	Mean	Median		(Min-Max)	SE	<i>n</i>
Ritchie Bay							
1991	1	34.1	34.0	a	(3–99)	0.87	522
1992	3	38.9	43.0	b	(3–111)	1.03	443
1995	1	24.0	16.0	c	(2–104)	0.94	512
1995	2	42.8	46.0	e	(1–123)	0.98	487
1995	4	34.4	35.0	a	(2–123)	1.07	495

2000	2	37.1	41.0	b z	(3–115)	1.12	447
2000	3	12.9	7.0	f	(2–111)	0.76	443
2000	4	33.7	34.0	ay	(3–124)	1.14	507
Marina Island							
1992	3	36.7	30.0	a z	(1–125)	1.16	510
2001	1	30.2	19.0	y	(3–112)	1.19	411
2001	2	16.1	9.0	x	(3–98)	1.09	289
2001	3	13.8	8.0	w	(3–116)	0.88	325

SE = standard error of mean, n = number of geoduck sampled. For each study area, medians followed by the same letter indicated age distributions were not significantly different (Mann-Whitney pair wise test $p > 0.05$), medians followed by a different letter indicated age distributions were significantly different (Mann-Whitney test, $P < 0.05$).

Figure 2. Proportion of geoduck necks showing in show factor plots (A) Ritchie Bay, and (B) Marina Island. Means (dots or x) and 95% CI (vertical lines) per year include 1–3 days of sampling.

RESULTS

Density

For Ritchie Bay, geoduck density remained highest over time in unharvested Plot 2 and lowest in the highly exploited Plot 3 (Fig. 1A). The removals over 3 y of practically all geoduck in Plot 3 caused geoduck densities to decline significantly by 1993 and to remain low, although there was a small density increase by 2000 (Fig. 1A). Although there was 0.62 exploitation rate of the geoduck in Plot 1 during 1991 (Table 2), with a consequent decline in geoduck density in 1992, densities recovered by 1995 (Fig. 1A). Geoduck densities in Plot 4 fluctuated between about 2.68 to 3.85 m^{-2} (Fig. 1A, Table 2).

Geoduck densities in the Marina Island experimental plots were considerably lower than those for Ritchie Bay (except for Plot 3 after 1992) (Fig. 1, Table 2). The removal of substantial numbers of geoduck reduced densities in both Marina Island Plots 2 and 3 (Fig. 1B, Table 2). Although Plot 3 had the highest and lowest density of the Marina Island plots in 1992 and 1996, respectively, Plot 3 densities recovered slightly to similar densities of control Plot 1 by 2001 (Fig. 1B, Table 2).

Exploitation rates were high especially in Plot 3 of Ritchie Bay and Marina Island, and in plots that had biosamples taken in already low density plots (Table 2). Mean estimates of exploitation values greater than 1.0 (i.e., Ritchie Bay Plot 3 in 1992, Marina Island Plot 2 in 1992) clearly were not possible and reflect the uncertainty of the density estimates of the survey method, but were possible within the lower 95% CI exploitation values (Table 2).

Show factors were generally recorded higher than 0.8 for most surveys in both study areas, except for Marina Island during 1993 to 1994 (Fig. 2) and for Ritchie Bay Plot 1 in August 1991 due to inclement weather (see also show factor in methods section). Strong winds, that could have affected geoduck to produce low show factors, were recorded at 30 and 28 km per hour from a northwest direction during July 5–6, 1993 respectively, and at 30 km per hour from a south east direction during June 4, 1994 near Marina Island. There were southeast winds of up to 43 km/hour recorded on August 7, 1991, near Ritchie Bay.

Age Frequencies

Following heavy harvesting there was a significant decrease in median ages (Table 3) and clear reduction in the densities of old geoduck in Ritchie Bay Plot 1 (Fig. 3A, 3B, 3C) between 1991 and 1995, Plot 3 (Fig. 3 F, 3G) between 1992 and 2000, and Marina Island Plot 3 (Fig. 4C, 4D) between 1992 and 2001. There was no significant change in geoduck median age for Ritchie Bay control Plot 4 between 1995 and 2000 (Table 3, Fig. 3H, 3I).

Recruitment

For Ritchie Bay, geoduck recruitment density at age 6 y, was generally higher for all plots in 2000 than in previous years (Table 4, Fig. 3). Recruitment within plots between years, was similar for Plot 1 between 1991 and 1995 but higher in 2000; was higher for Plot 2 in 2000 than 1995; higher for Plot 3 in 2000 than 1992; and similar for control Plot 4 in 1995 and 2000 (Table 4, Fig. 3). Geoduck recruitment density between Plots 1, 2, and 4 in 1995 was similar, and recruitment for all four plots in 2000 was similar.

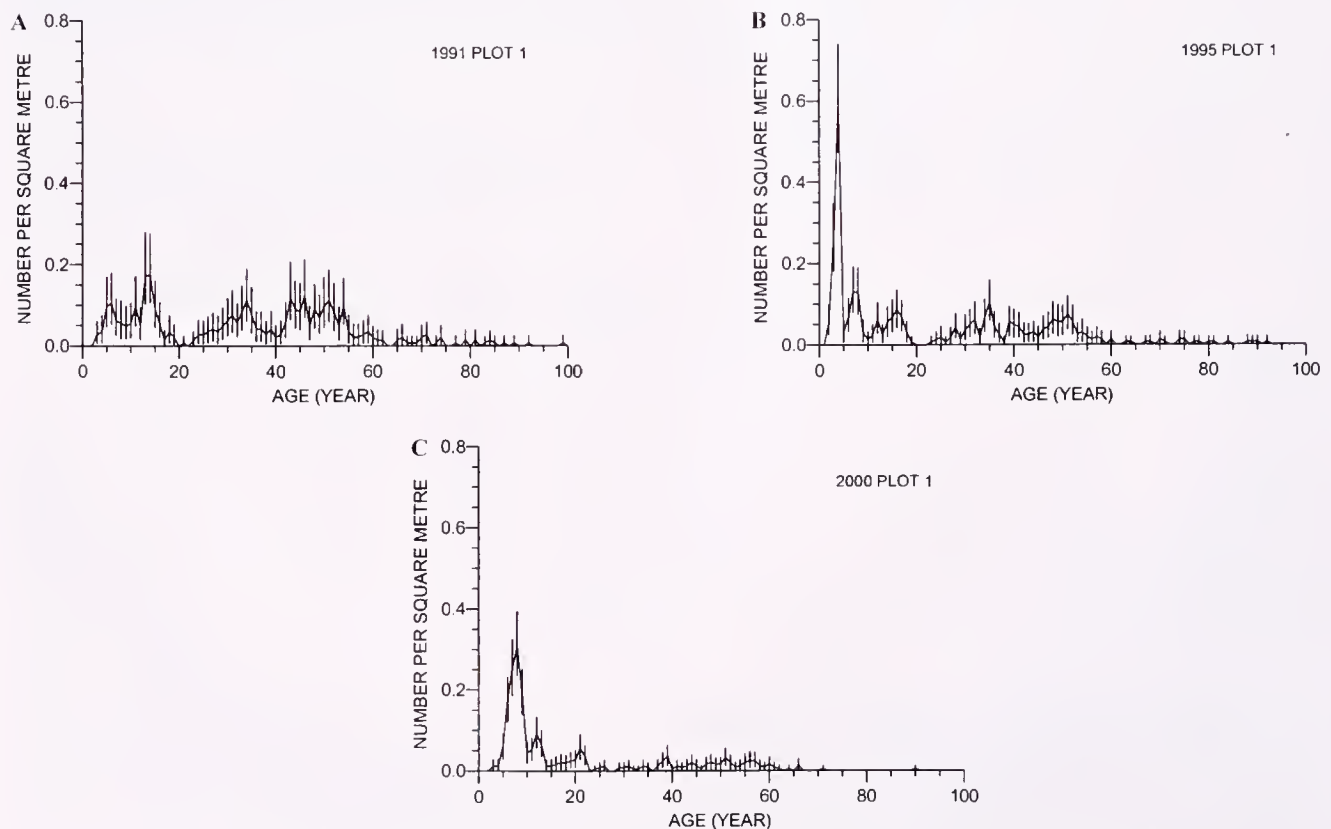

Figure 3. Density age frequencies for geoduck in the experimental plots of Ritchie Bay. Vertical lines are 95% CI.

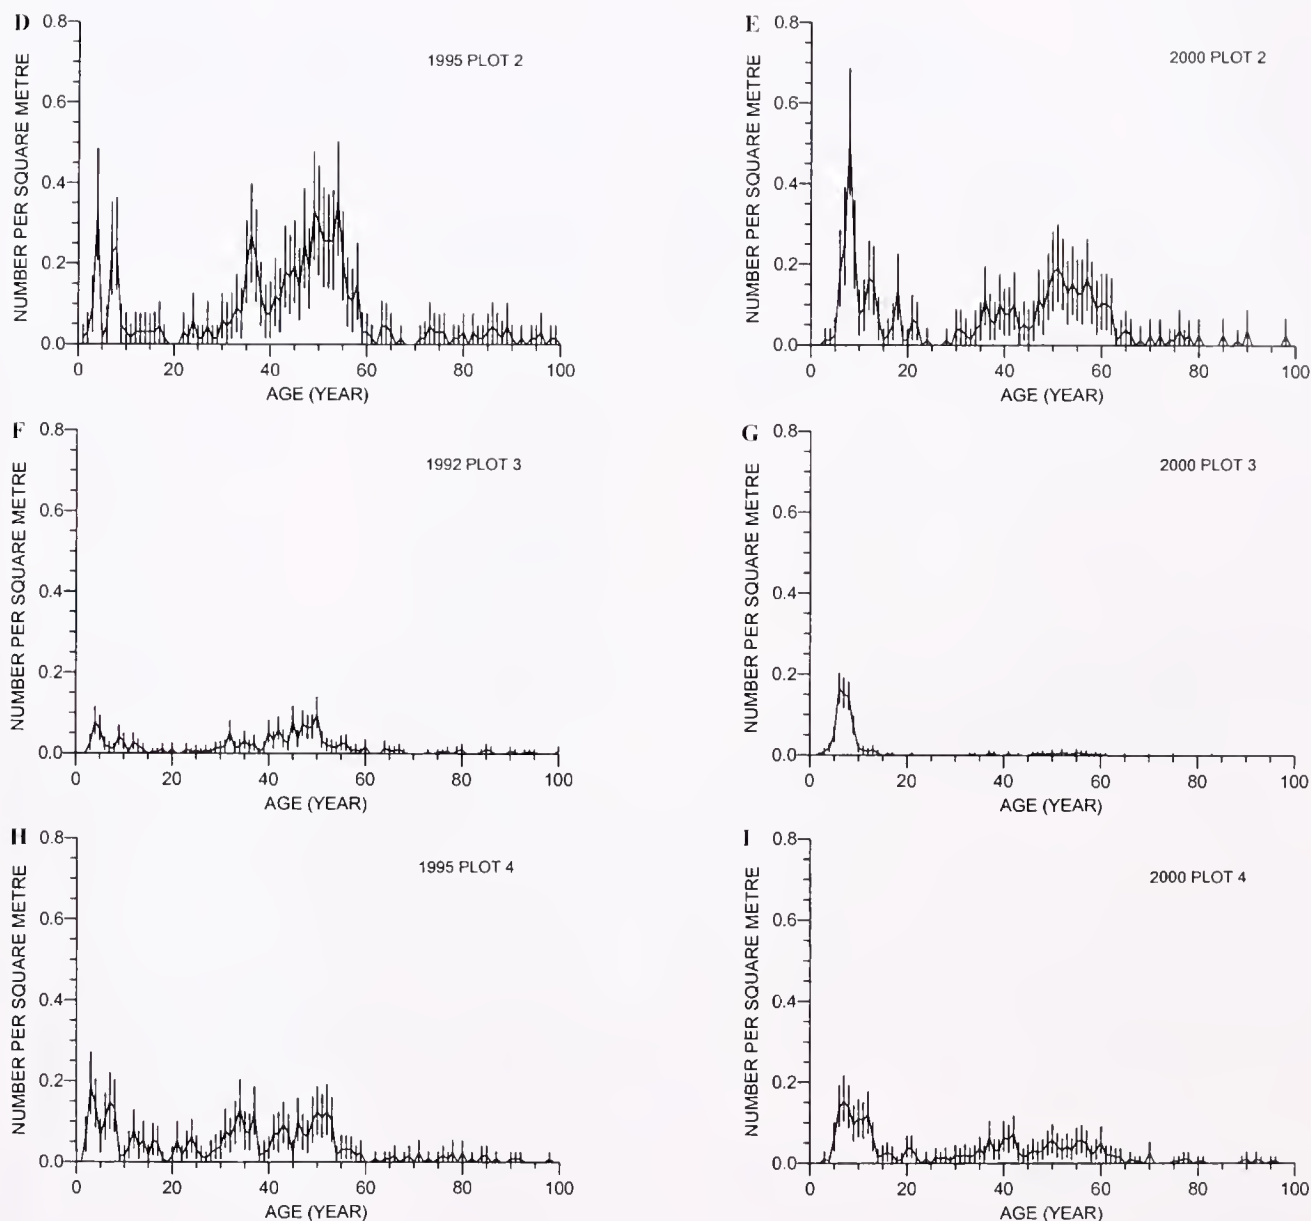

Figure 3. Continued.

For Marina Island, geoduck recruitment density at age 7 y, was slightly higher for Plot 3 in 2001 than 1992 (Table 4, Fig. 4). Plots 2 and 3 had higher geoduck recruitment than Plot 1 in 2001 (Table 4, Fig. 4).

Geoduck recruitment at Ritchie Bay was well above that for Marina Island in the last 10 y (Fig. 3, 4, Table 4). The highest density for each plot at a particular age and year: for Ritchie Bay Plot 1 was 0.60 at 4 y in 1995, 0.31 at 8 y in 2000; Plot 2 was 0.33 at 4 y in 1995, 0.51 at 8 y in 2000; Plot 3 was 0.08 at 4 y during 1992, 0.16 at 6 y in 2000; Plot 4 was 0.18 at 3 y in 1995, 0.15 at 7 y in 2000 (Fig. 3); and for Marina Island Plot 1 was 0.014 at 8 y in 2001; Plot 2 was 0.029 at 8 y in 2001; Plot 3 was 0.038 at 9 y in 1992, and 0.042 at 8 y in 2001 (Fig. 4).

The influence of artificial seeding on the density of the 1991 cohorts, 4 and 9 y later, was suggested by the higher geoduck densities in Plot 1 (4.28 and 1.90 times) and Plot 2 (2.36 and 2.40

times) compared with the geoduck densities in unseeded Plot 4 during 1995 and 2000, respectively (Table 5; Fig. 3).

Growth

The results on the geoduck growth curves (Table 6, Fig. 5) and the Kimura pair-wise comparisons (significant differences at $P < 0.05$) (Table 7) were grouped as follows.

Within Each Plot Between Years

The Brody growth coefficients, or k values, for geoduck in Ritchie Bay Plots 1, 2, and 4 were significantly higher in 1995 than for the same plots in 1991 and 2000. In contrast, the k value for Ritchie Bay Plot 3 was significantly higher in 2000 than in 1992. The k value for Marina Island Plot 3 was significantly higher in 2001 than 1992.

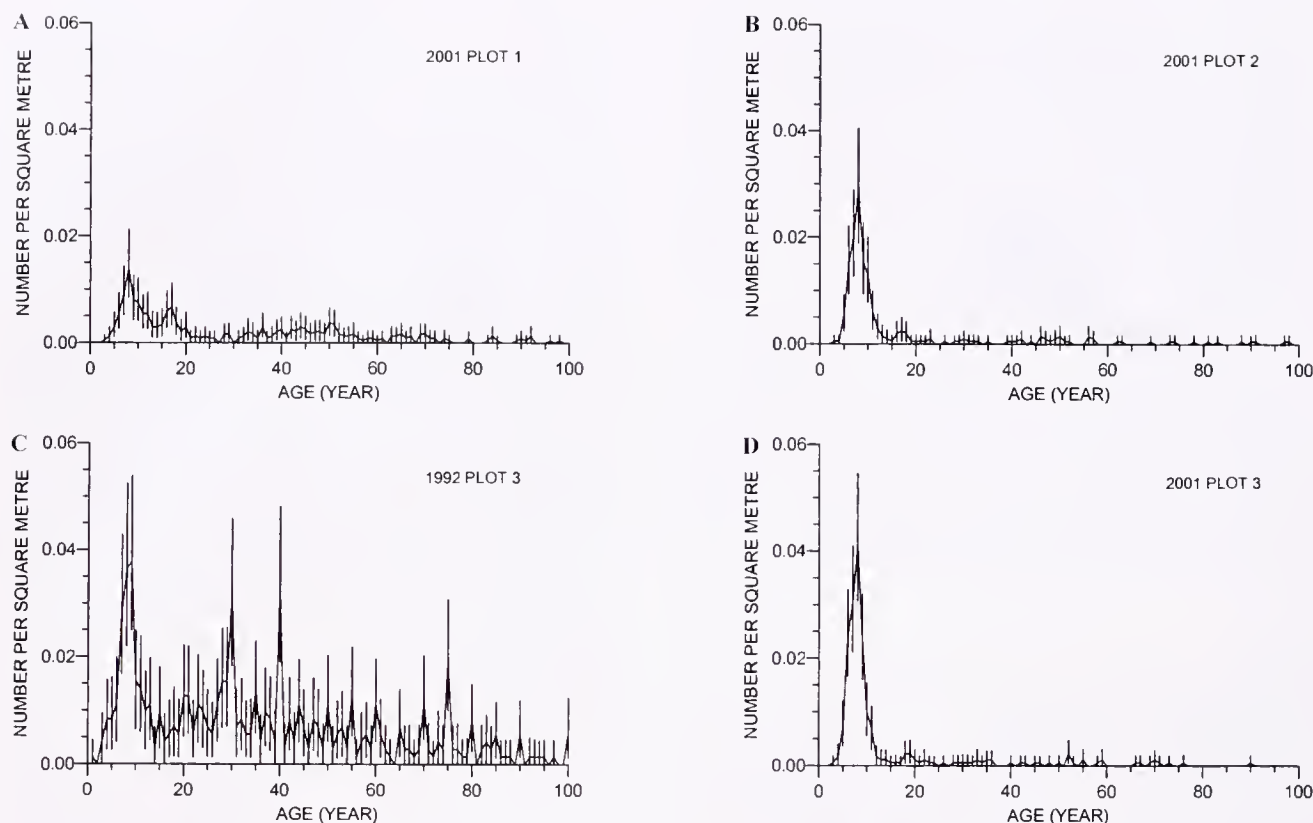

Figure 4. Density age frequencies for geoduck in the experimental plots of Marina Island. Vertical lines are 95% CI.

The L_{∞} values were significantly higher, prior to the removals, for most Ritchie Bay plots, (i.e., Plot 1 higher in 1991 than 1995 Plot 1 in 1995 and 2000 were not significantly different), Plot 2 and 4 larger in 1995 than 2000, Plot 3 larger in 1992 than for 2000, and Marina Island Plot 3 larger for 1992 than for 2001. In contrast, the L_{∞} values for Ritchie Bay Plot 4 were not significantly different between 1995 and 2000.

CI, confidence interval.

Between Plots Within Similar Years

The k value(s) for geoduck in Ritchie Bay Plot 1 in 1991 was not significantly different to Plot 3 in 1992; for 1995 Plots 1, 2 and 4 were not significantly different; for 2000 Plots 1, 2, and 4 were not significantly different but all three were significantly lower than that for Plot 3. The k values were not significantly different for Marina Island Plots 1, 2, and 3 in 2001. The k value was higher for Marina Island Plot 3 in 1992 than for Ritchie Bay Plot 1 in 1991 and Plot 3 in 1992.

The L_{∞} values were significantly different between most

1,2,3	2001	136.1 (135.0–137.1)	0.252 (0.244–0.263)	11.35 (10.84–12.03)	826

Values in brackets are approximate 95% confidence intervals. The von Bertalanffy parameter t_0 was set at zero. Mean L_{∞} and k values followed by the same letter and column are not significantly different ($P > 0.05$); whereas values not followed by the same letter are significantly different ($P < 0.05$) using the Kimura method (see text and Table 6 for more details). Comparisons of geoduck growth in plots between study areas were conducted only for plots that were sampled in the same year or one year apart. σ^2 is the mean square error of the model.

Ritchie Bay plots during 1995 and during 2000, except Plot 2 and 4 were not significantly different during 2000. The L_{∞} values for 2001 at Marina Island Plots 2 and 3 were not significantly different, but both were different from Plot 1. The L_{∞} value for Marina Island Plot 3 in 1992 was not significantly different for Ritchie Bay Plot 1 in 1991, but significantly different for Plot 3 in 1992.

Between Plots and Years

The k values were significantly different when comparing between most plots and years, except for Ritchie Bay Plots 1, 2, and 4 in 1995, which were similar to Plot 3 in 2000.

The L_{∞} values were not significantly different between Ritchie Bay Plot 1 in 1991 with Plot 2 and 4 in 1995, with Plots 2 and 4 in 2000, and Plot 4 in 1995 with Plot 2 in 2000.

Both k and L_{∞} geoduck growth values were significantly higher for the combined Ritchie Bay Plots 1, 2, 3, and 4 data in 2000 compared with the combined Marina Island Plots 1, 2, and 3 data in 2001.

Relation Between Density, Recruitment, and k

No significant ($P > 0.05$) relationships between recruitment and density, k and recruitment, or k and density could be detected when using data from all plots and years in the Ritchie Bay or the Marina Island study areas.

DISCUSSION

This study provides, for the first time, information on *P. abrupta* population biology from a 9-year study of experimental plots in two different areas of southern BC. Heavy exploitation for the first 3 years in Plot 3 of both Ritchie Bay and Marina Island substantially reduced geoduck population densities, reduced the average age (by removing old individuals), but thereafter densities slowly increased due to recruitment. A similar trend was observed for geoduck that were fished heavily only for the first year, but the

initial recovery was more rapid in geoduck populations for Plot 1 of Ritchie Bay than for Plot 2 of Marina Island. Geoduck densities in the control plots fluctuated over time, but CIs often overlapped between years. Factors causing geoduck age densities to fluctuate could have included removals for biosamples, fishery induced mortality (harvesting methods causing incidental injuries to the remaining unfished geoduck), geoduck natural mortality (e.g., Zhang & Campbell 2004), recruitment and growth rates influenced by environmental conditions. The fluctuation was also likely related to the accuracy of the density estimates. Although experienced commercial divers were used for all density estimates, occasional poor visibility, due to plankton, drift algae, silt, or strong current at Ritchie Bay could have influenced the results.

Geoduck densities surveyed in the experimental plots were generally within the density range reported from surveys in similar regions: west coast of Vancouver Island ($0.29\text{--}3.34\text{ m}^{-2}$) (Hand & Dovey 1999, Hand & Bureau 2000) and Inside waters including Georgia Strait ($0.18\text{--}0.70\text{ m}^{-2}$) (Hand & Bureau 2000). The high density values of $5\text{--}7\text{ m}^{-2}$ found in Plot 2, and generally from Ritchie Bay by Fyfe (1984) ($4.00\text{--}7.69\text{ m}^{-2}$), were unusual for southern BC and only matched and surpassed by areas surveyed in northern BC with densities as high as 10.27 m^{-2} found in the Moore Islands (Hand & Bureau 2000). A reason for the high geoduck density at Ritchie Bay was probably because of the area being closed to commercial fishing and designated as a research reserve since 1980 (Fyfe 1984). In contrast, the area around Marina Island was heavily harvested during 1978–1989 and closed to commercial fishing since 1990 (Campbell et al. 1996b).

Geoduck percentage shows were high ($>80\%$) in both study areas for most of the summers studied. Low show factors ($<80\%$) recorded in the Marina study area during 1993–1994 were preceded by strong winds of $28\text{--}30\text{ km per hour}$ a few days prior to the density surveys. High winds probably caused the geoduck to retract their siphons via shifting sand or debris on the substrate surface at the study sites where depths were fairly shallow (<17

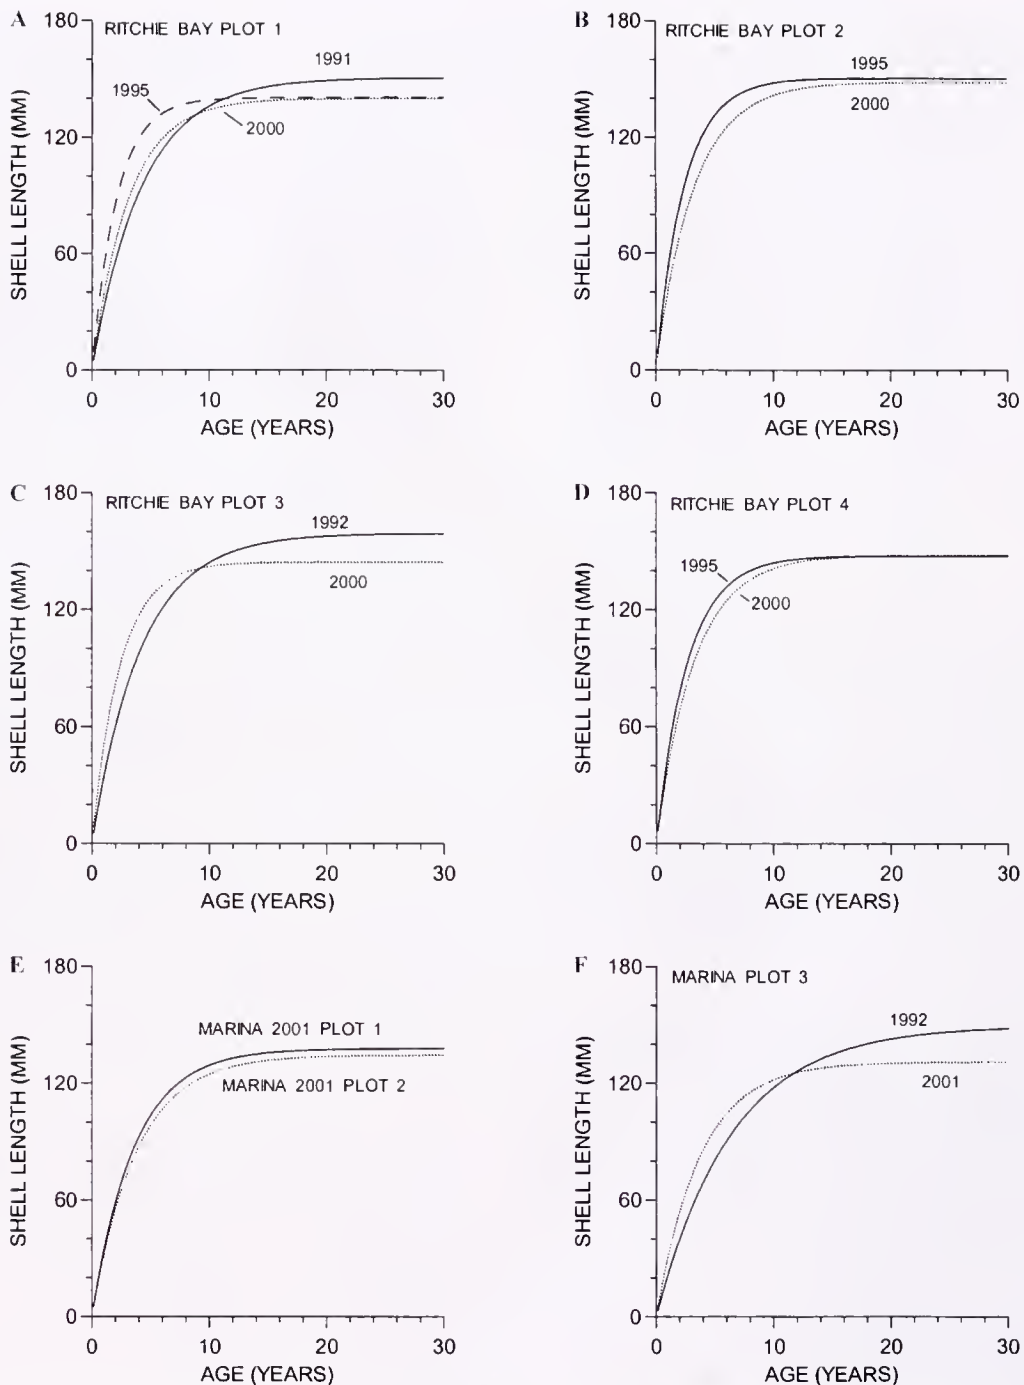

Figure 5. Mean geoduck growth curves from the experimental plots of Ritchie Bay and Marina Island derived from equation coefficients in Table 6. Curves shown are for only geoduck ≤ 30 y old to clearly show the rapid growth increase to the asymptotic shell length.

m). Variation in the direction, duration, and/or intensity of wind may have influenced the level of geoduck show factor in different locations, depending on topography and depth of the area. Low salinity caused by precipitation and rainwater runoff from nearby land due to storms may also be other factors affecting geoduck shows. Show factor estimates could be important in estimating density, especially when density surveys are conducted after a storm or during fall-winter months. The percent of geoduck in a bed "showing" their siphons at or above the substrate surface has been found in different studies to vary under different environ-

mental and physiologic conditions. A number of authors (Goodwin 1973, Goodwin 1977, Cox & Charman 1980, Turner & Cox 1981, Fyfe 1984) have reported that the highest seasonal percentage of shows ($>80\%$) was during the summer (April to September) when feeding and reproduction occurred and the lowest ($<50\%$) was during the winter (November to February) when many geoduck were inactive. Shows were highest when local water currents were not excessive and there was no mechanical disturbance of the bottom (Goodwin 1977). Campbell et al. (1996a) documented the percentage shows was reduced from about 80% to 65% after a

storm in a wave-exposed area, but returned to about 80% within 2–3 wk of the storm event.

The recruit age for geoduck was lower for Ritchie Bay (6 y) than for Marina Island (7 y) because geoduck growth rates were highest in Ritchie Bay of the two study areas. This suggests that growth rates, physical or physiologic characteristics and age estimation for geoduck from different locations need to be examined prior to defining an age for a particular type of recruitment, (e.g., neck size for fishery purposes or for age at maturity, Campbell & Ming 2003).

Recruitment was variable temporally and at both small and large spatial scales. Recruitment was generally higher for the Ritchie Bay plots during 2000 and for Marina Island Plot 3 during 2001 than the previous years. Recruitment was considerably higher for geoduck in Ritchie Bay during 2000 than for Marina Island during 2001. Recruitment was similar for Ritchie Bay plots with high or low geoduck densities during 2000. Spatial and temporal variability in geoduck recruitment have been reported previously (Breen & Shields 1983, Harbo et al. 1983, Fyfe 1984, Goodwin & Shaul 1984, Sloan & Robinson 1984, Breen et al. 1991, Noakes & Campbell 1992, Hand & Dovey 1999, Orensanz et al. 2000, Bureau et al. 2002, Bureau et al. 2003). Recruitment may be influenced by various factors (e.g., size of breeding brood stock providing progeny, predation on the larval and early juvenile stages, environmental variables such as local currents, and/or general temperature trends affecting larval and early juvenile growth and survival). The timing of reproduction may also affect larval settlement and juvenile recruitment through food availability and growth rates. Gribben et al. (2004) found that differences in the timing of spawning between two *P. zelandica* populations could be attributed to latitudinal temperature gradients. Bureau et al. (2002, 2003) found that age frequency data of geoduck sampled throughout BC during the 1993 to 2002 period indicated strong geoduck recruitment trends, which might be linked to a general warming trend or El Niño events.

Local geoduck recruitment also could be affected by the physical disturbances of local fishing events. The study of Goodwin and Shaul (1984), which lasted approximately 20 mo and sampled >1 year-old geoduck with a venture dredge, suggested that fishing could have an adverse effect on recruitment in the short term. Our 9-y study examined the long term side effects of fishing on recruitment, since young geoduck (<4 y) could not be detected until the survivors recruited into 6–7 y age groups and became visible to divers several years following the fishing event. In this study, we did not detect any long-term effect of heavy fishing or low geoduck densities on subsequent recruitment. However, Zhang and Campbell (2004) found from retrospective age structure modeling of these populations that recruitment was generally lower after fishing geoduck in Plot 3 compared with the other three plots from Ritchie Bay suggesting that fishing, low geoduck densities or juvenile mortality could have influenced recruitment in Plot 3, at least in the first 1–3 y after fishing. Assuming there was sufficient geoduck larval supply from other areas, we concluded (this study and Zhang & Campbell 2004) that a heavy fishing event could reduce local recruitment in the short term, but probably not influence recruitment in the long term (e.g., >3 y). However, other environmental or biologic factors could mask the effects of fishing on recruitment as was observed in the Marina Island study area. In contrast to the Ritchie Bay observations, at Marina Island, the control unfished Plot 1 had poor recruitment compared with the other two fished plots.

TABLE 7.

Results of the likelihood ratio tests using the Kimura (1980) method to compare von Bertalanffy growth parameters of geoduck between years and plots for Ritchie Bay and Marina Island.

Hypotheses: H1: Common k , i.e., $L_{\infty}(1) \neq L_{\infty}(2)$ and $k(1) = k(2)$; H2: Common L_{∞} , i.e., $L_{\infty}(1) = L_{\infty}(2)$ and $k(1) \neq k(2)$; H3: Common k and L_{∞} , i.e., $L_{\infty}(1) = L_{\infty}(2)$ and $k(1) = k(2)$. The null hypothesis rejected at $\alpha < 0.05$ level. P-values of 0 are <0.005.

Artificial seeding of Ritchie Bay Plots 1 and 2 provided a slight increase above the natural recruitment. Much (96% to 99%) of the large number of seed released (estimated to be a mean 16.0 m^{-2}) into these two plots probably did not survive. Without providing adequate protection from predators (e.g., fish, crabs, and starfish) (Goodwin & Pease 1989) artificial geoduck seeding was considered not economically feasible for enhancement of natural geoduck populations (Beattie 1992, Beattie & Blake 1999, Clapp 2000).

Growth characteristics of geoduck from different plots and years varied considerably. Although no simple broad statistical relationship could be detected between geoduck density and the growth parameters when all plots and years for each study area were combined some interesting observations on geoduck growth could be made. Following removal of many geoduck in a plot, subsequent growth characteristics indicated a lowering of the apparent mean max asymptotic length (L_{∞}) and an increase in the Brody growth coefficient (k) of the von Bertalanffy growth model. Removal of old individuals from a geoduck population such as in Ritchie Bay Plots 1 and 3 and Marina Island Plot 3 (Fig. 1, 3, and Table 3) probably influenced the L_{∞} to decline and the Brody growth function k values to increase (Fig. 5 and Table 6). Where there was no major exploitation and geoduck densities remained similar over time such as in Ritchie Bay Plots 2 and 4, L_{∞} values remained similar, but k values varied with time. Reasons for the differences in *P. abrupta* growth rates between areas and plots could be generally attributed to various environmental and bio-

logic factors associated with different habitats (e.g., depth, substrate type, temperature, exposure to water surge activity, pollution, food availability, geoduck density, and or genetic characteristics) (Breen & Shields 1983, Harbo et al. 1983, Goodwin & Shaul 1984, Goodwin & Pease 1991, Noakes & Campbell 1992, Hoffmann et al. 2000, Bureau et al. 2002).

NATURAL MORTALITY AND RECRUITMENT RATES OF THE PACIFIC GEODUCK CLAM (*PANOPEA ABRUPTA*) IN EXPERIMENTAL PLOTS

ZANE ZHANG AND ALAN CAMPBELL*

Shellfish Stock Assessment Section, Pacific Biological Station, 3190 Hammond Bay Road, Nanaimo, British Columbia, V9T 6N7, Canada

ABSTRACT Experiments were conducted in Ritchie Bay on the west coast of Vancouver Island and Marina Island inside the Strait of Georgia, British Columbia, to examine the natural mortality (M) of geoduck, *Panopea abrupta*, and impact of harvesting on recruitment to 1 year of age. We used age-structured models to estimate M and recruitment rates. The overall mean M was estimated to be 0.039 (0.0046 SE) using Monte Carlo simulations and to be 0.036 (0.0027 SE) using the Bayesian method. Severe harvesting (>90% removal) had an adverse impact on short-term (≤ 3 y) recruitment, but did not show evidence of long-term (>3 y) impact on geoduck recruitment in the Ritchie Bay experimental plots. In contrast, the most severely harvested plot of the Marina Island plots received the highest recruitment both in the short-term and long-term. However, this plot also obtained the highest recruitment before the experiment, suggesting that local hydrodynamics may have played a significant role in the geoduck larval settlement / recruitment rates in the Marina Island study area.

KEY WORDS: bivalvia, geoduck, *Panopea abrupta*, modeling, natural mortality, recruitment, larval settlement

INTRODUCTION

The Pacific geoduck clam, *Panopea abrupta*, (Conrad 1849) (Bivalvia: Hiatellidae), is found in subtidal coastal areas along the northeast Pacific from California to Alaska (Coan et al. 2000). *Panopea abrupta* supports commercial fisheries in Washington State, British Columbia (B.C.) and Alaska (Campbell et al. 1998, Bradbury & Tagart 2000). In an attempt to understand the effects of fishing on the population biology of geoduck, Campbell et al. (2004) followed geoduck population density, recruitment, and growth under different controlled exploitation levels in experimental plots of southern B.C. over a 9-y period. In our study we extend the analyses of Campbell et al. (2004) by using a retrospective age structured model to determine natural mortality and recruitment rates of geoduck in these plots. Campbell et al. (2004) defined recruitment rate as the density of age 6 or 7 y geoduck growing into the population that was fully vulnerable to fishing. In this study, however, we define recruitment rate as the number of age 1-y geoduck per m^2 , to obtain a few more years of density data for young geoduck that settled after the beginning of the experiment. Unless specified, recruitment refers to 1-year-old geoduck. Understanding natural mortality and impact of harvesting on recruitment are important to managers in establishing sustainable harvest rates or annual fishing quotas for geoduck fisheries (Bradbury & Tagart 2000, Hand & Bureau 2000, Orensanz et al. 2000).

MATERIALS AND METHODS

Two experiments were conducted, one in Ritchie Bay on the west coast of Vancouver Island and the other in Marina Island inside the Strait of Georgia, B.C. The experiment started in 1991 and ended in 2000 in Ritchie Bay with four experimental plots; the first three had an area of 2440 m^2 each, and the fourth was 2500 m^2 . The experiment started in 1992 and ended in 2001 in Marina Island with all three experimental plots having an area of 2500 m^2 each. Because details of the study areas can be found in Campbell et al. (2004), we only summarize the relevant field procedures.

The general harvest treatment in each plot for Ritchie Bay was

(1) moderate, (2) none, (3) heavy, and (4) none (control), and for Marina Island was (1) none (control), (2) moderate, and (3) heavy. A large number of geoduck were removed commercially in the first experimental year from Plot 1 and in the first 3 y from Plot 3, whereas no geoduck were removed commercially from Plot 2 or 4 in Ritchie Bay. In Marina Island, geoduck were removed commercially in the first experimental year from Plot 2 and in the first 3 y from plot 3, whereas no geoduck were removed commercially from Plot 1. In addition, about 500 geoduck were removed as bio-samples each time in 2 to 3 different years from each of the four plots in Ritchie Bay. In Marina Island, bio-samples of about 300 to 400 geoduck were also removed from each of the three plots during 2001, and about 500 geoduck were also taken from Plot 3 during 1992. The bio-samples were used to determine geoduck age frequencies. Age of each geoduck was estimated using the acetate peel method of Shaul and Goodwin (1982).

In most of the experimental years, dive surveys were conducted to assess the abundance of geoduck in each plot in both experimental areas. Density surveys were always conducted prior to removal of geoduck. All geoduck densities were adjusted for show factor (a detectability proportion) as provided by Campbell et al. (2004). To determine if seeding of hatchery-raised juvenile geoduck could supplement natural recruitment, Campbell et al. (2004) artificially seeded plot 1 and plot 2 of Ritchie Bay, with <0.5-y-old hatchery-raised juvenile geoduck during September 1991.

Age-structured modeling was used to estimate natural mortality (M) and recruitment rates. We first estimated vulnerabilities of young geoduck to the divers to estimate abundance of young geoduck using the catch data. We estimated M by comparing model-derived abundances with survey-derived abundances. Using the calculated M s and available bio-samples, we estimated 1-y-old geoduck densities during and 1–10 y prior to the experiment. Mortality rate for geoduck was considered to be high during the early benthic life stage (Goodwin & Shaul 1984), and decreased quickly after age 1 year (Sloan & Robinson 1984). Thus, the density of 1-y-old geoduck was used to denote the recruitment rate and to reflect the relative larval settlement rate of the previous year.

Vulnerability to Fishing

One-year-old Geoduck did not appear to be vulnerable to divers, as only 1 out of 4354 aged geoduck was estimated to be age

*Corresponding author. E-mail: ZhangZ@pac.dfo-mpo.gc.ca

1 y. We assumed that geoduck started to be partially vulnerable at age 2 y and fully vulnerable at age 6 y in Ritchie Bay and 7 y in Marina Island (Campbell et al. 2004). We used an exponential model to describe the vulnerability of geoduck between ages 2 y and fully vulnerable age (FV_α) of ages 6 y or 7 y:

$$V_\alpha = \frac{(\alpha - 1) \times \exp(\beta \times \alpha)}{(FV_\alpha - 1) \times \exp(\beta \times FV_\alpha)} \quad (1)$$

where α is the age and β is the parameter of the model. The value of β is estimated by fitting a multinomial probability model to the observed age frequencies. The likelihood for observing the age composition in a bio-sampling occasion was estimated based on the age composition from the previous bio-sampling occasion and vulnerability of geoduck at each age. Only geoduck between ages 2 and FV_α years in one sampling occasion were used to calculate the probabilities for age composition for geoduck between $2 + n$ and $FV_\alpha + n$ years in the next sampling occasion n years later. Geoduck $>FV_\alpha$ were not considered, because the likelihood for observing the age composition for geoduck $>FV_\alpha + n$ in the next sampling occasion was not affected by different values of β .

Only age-composition data from Plots 1, 2, and 4 in Ritchie Bay were used for the vulnerability estimation; data from Plot 3 in Ritchie Bay were not used because they would have been affected by commercial removal of geoduck during two sampling occasions, and there was an insufficient number of bio-samples over time from Marina Island.

The density of geoduck at age α ($2 \leq \alpha \leq FV_\alpha$) was estimated to be:

$$D_{j,\alpha} = \frac{\hat{D}_j \times p_{j,\alpha}}{V_\alpha} \quad (2)$$

where \hat{D}_j and $p_{j,\alpha}$ are the survey-derived geoduck density and the proportion of geoduck of age α in bio sampling occasion j .

In the next bio-sampling occasion n years later, the surviving geoduck of age α would become age $\alpha + n$. We assumed that natural mortality rate was invariant with ages. Thus, the proportion of vulnerable geoduck at age $\alpha + n$ in bio-sampling occasion $j + 1$ was estimated to be:

$$p_{j+1,\alpha+n} = \frac{D_{j,\alpha} \times V_{\alpha+n}}{\sum_{\alpha=2}^{FV_\alpha} D_{j,\alpha} \times V_{\alpha+n}} \quad (3)$$

The estimated proportions were treated as probabilities for the multinomial distribution. The likelihood for observing the age composition at the bio-sampling occasion $j + 1$ was calculated as:

$$L_{j+1} = \prod_{\alpha=2}^{FV_{\alpha+n}} (p_{j+1,\alpha+n})^{N_{j+1,\alpha+n}} \quad (4)$$

where $N_{j+1,\alpha+n}$ is the observed number of geoduck at age $\alpha + n$ at bio-sampling occasion $j + 1$. The overall likelihood for observing the age compositions in all bio-sampling occasions except for the first ones in all the plots was:

$$L = \prod_{Plots} \prod_j L_{j+1}$$

The unknown parameter β in Eq. 1 was estimated by trials of various values until the maximum likelihood was reached.

To assess the variation in estimated parameter β , age composition in each of the bio-samples was bootstrapped by resampling

with replacement to produce a simulated sample of the same size. The simulated data sets were used to estimate the parameter β in the same way as described earlier. Nine hundred and ninety-nine data sets were generated producing 1000 estimates of β , from which the mean and standard error for β were calculated.

Natural Mortality Rate

We reconstructed population age structure using the bio-samples in the last experimental year. M was estimated to be the value that resulted in the best match between the model-derived abundances and the survey-derived abundances. We estimated variations in M with Monte Carlo simulations (i.e., age composition, density, and the value of β) of the vulnerability model are randomly regenerated. For a comparison, the Bayesian method (Carlin & Louis 1996) was also used to estimate M .

The minimum age was set at 2 y for each year. The maximum age was set to be 30 y for the last experimental year. The maximum age for other years was 1 year younger than for the subsequent year. Geoduck older than the maximum age were pooled together to form a maximum plus age group. For instance, geoduck older than age 30 y for the last year were lumped to be age 30 + y. In the mathematical equations, the pooled age group was expressed as an age 1 year older than the maximum age considered. For instance, age 31 y for the last year means age 30 + y in the expression.

The number of geoduck at age α in the last bio-sampling year ($y = 2000$ for Ritchie Bay and $y = 2001$ for Marina Island) was estimated based on the survey-derived density (\hat{D}_y), area of the plot (S), the proportion of geoduck at age α in the samples ($p_{y,\alpha}$), and vulnerability of geoduck at age α (V_α):

$$N_{y,\alpha} = \hat{D}_y \times S \times p_{y,\alpha} / V_\alpha \quad (5)$$

To reconstruct age compositions in the past, we replaced the amount of geoduck removed commercially and/or due to bio sampling back to the reconstructing population. We used the proportion of geoduck at each age in the bio-samples to estimate the amount of removal at each age, if bio-samples were taken in that year. Otherwise, the proportion was estimated based on the reconstructed age composition in the subsequent year. The proportion of vulnerable geoduck at age α in year y was:

$$\begin{cases} VP_{y,\alpha} = p_{y,\alpha} & \text{with bio-samples in year } y \\ VP_{y,\alpha} = \frac{N_{y+1,\alpha+1} \times V_\alpha}{\sum_{\alpha=2}^{MA_{y+1}} N_{y+1,\alpha+1} \times V_\alpha} & \text{without bio-samples in year } y \end{cases} \quad (6)$$

where MA_{y+1} is the maximum age considered for year $y + 1$. The number of geoduck of age α removed in year y was estimated to be:

$$RM_{y,\alpha} = VP_{y,\alpha} \times TR_y \quad (7)$$

where TR_y is the total number of geoduck removed in year y . The number of geoduck at age α in year y ($y < \text{last experimental year}$) was back-calculated from the estimated number of geoduck at age $\alpha + 1$ in year $y + 1$:

$$N_{y,\alpha} = N_{y+1,\alpha+1} \times \exp(M) + RM_{y,\alpha} \quad (8)$$

where M is the natural mortality rate to be estimated in the model. Eq. 6–8 were repeatedly used to estimate abundance of geoduck at each age in each of the previous years.

The likelihood for the reconstructed population was determined by comparing the model-estimated abundances with the survey-estimated abundances. Because abundances derived from surveys indicated the vulnerable population abundances, the likelihood was calculated as follows:

$$L = \frac{1}{se_v} \exp \left(- \frac{\sum_y (VN_y - \hat{N}_y)^2}{2(se_v)^2} \right) \quad (9)$$

where N_y and se_v are, respectively, the number of geoduck and standard error estimated from the survey, and VN_y is the model-estimated vulnerable number of geoduck in year y when bio-samples were taken:

$$VN_y = \sum_{\alpha=2}^{MA_y+1} N_{y,\alpha} \times V_{\alpha} \quad (10)$$

When data from all the plots were analyzed simultaneously, the likelihood was simply the product of likelihood for each of the plots:

$$LL = \prod_{Plots} L.$$

Monte Carlo Simulation

A grid search method was used to find the value of M , which maximized the likelihood. Errors in the estimations were evaluated through simulations. Age composition in the bio-samples taken in the last year was bootstrapped (Efron & Tibshirani 1993) by re-sampling with replacement to produce a simulated sample of the same size. Geoduck densities in the last year were randomly regenerated from a normal distribution with the mean and standard error estimated based on the survey. The parameter β in the vulnerability model was also randomly regenerated from a normal distribution with the estimated mean and standard error. The calculation procedures described earlier were repeated for each set of regenerated data. Nine hundred and ninety-nine data sets were regenerated, resulting in 1000 sets of estimates of M .

Bayesian Analysis

The parameters in the Bayesian model include M , β , and density or densities in the last bio-sampling year (one for each plot). Uniform prior probability distributions were applied to all the parameters. The range was constrained between 0 and 0.3 for M and larger than 0 for densities. In the case that only one plot is used in the estimation, the posterior probability could be expressed as follows:

$$P \propto L \times \frac{1}{SEd} \exp \left(- \frac{(D - \hat{D})^2}{2 \times SEd^2} \right) \times \frac{1}{SEb} \exp \left(- \frac{(\beta - \hat{\beta})^2}{2 \times SEb^2} \right) \quad (11)$$

where L is the likelihood calculated using Eq. 9; D , \hat{D} and SEd are, respectively, the regenerated true density, survey-estimated density, and standard error in the last bio-sampling year; β , $\hat{\beta}$ and SEb are, respectively, the regenerated true value, estimated value for the parameter of the vulnerability model and associated standard error. When all plots were used simultaneously, the posterior probability was:

$$PP = \prod_{Plots} P.$$

The Gibbs sampler (Geman & Geman 1984) was used to generate marginal likelihood distribution for M . The *Gibbs* sampler is an approach for sequentially taking random samples for each parameter from its full conditional distribution, which is a probability distribution conditional on the data and on the current values of all the other parameters (Gelfand & Smith 1990). To construct the full conditional distribution for a parameter, we just picked the terms in the posterior distribution which involve the parameter (Gilks et al. 1996). Thus, the full conditional distribution is proportional to the posterior probability. When a full conditional distribution can be expressed in a special form, sampling can be easily conducted. The full conditional distributions for M , D and β , however, cannot be expressed as some special forms. We used the Adaptive Rejection Metropolis Sampling algorithm developed by Gilks et al. (1995) to take random samples.

To start the Gibbs sampler, the initial values for M , densities, and β were set to be the estimated means using the Monte Carlo simulation method described earlier. Samples of the first 500 cycles were ignored as a "burn-in" period for the initial algorithm setup. Altogether, 20,500 cycles were conducted. To reduce autocorrelation every 20th sample was saved after the burn-in period. The MCMC samples passed the convergence test of Heidelberger and Welch (1983) provided by the computer program CODA (Convergence Diagnosis and Output Analysis Software for Gibbs sampling output version 0.40) (Best et al. 1997).

The Bayesian method described earlier assumed that the estimated age for each sample represents the true age with no errors. However, age composition in the bio-samples taken in the last year was bootstrapped, when the Monte Carlo method was used to estimate the variation in M . For a more comparable comparison of the estimated variations in M between the two methods, age composition in the bio-samples collected in the last year was also bootstrapped after each random sampling of M , β , and density or densities.

Recruitment

To compare recruitment rates before and after the beginning of the experiment, population age structures were constructed from the last experimental year back to 10 y before the beginning of the experiment for each plot. Because bio-samples collected in earlier years were likely to be of higher significance in determining recruitment before the experiment, bio-samples collected in all the years were independently used in the reconstruction. Both the estimated M for the individual plot and overall mean M using the Bayesian method with bootstrap of the age composition were separately applied for Ritchie Bay data. Only the overall mean M estimated for geoduck in Ritchie Bay was used for each plot in Marina Island, because natural mortality rates could not be reliably estimated for geoduck in each experimental plot of Marina Island.

The maximum and minimum ages considered for each year were the same as described earlier. The minimum age was age 2 y for each year; the maximum age was age 30 y for the last experimental year, and the maximum age for other years was just 1 year younger than for the subsequent year. The reconstruction was also conducted analogously as described earlier.

Multiple estimates of the number of 1-y-old geoduck were obtained for each year, when there were bio-samples from multiple bio-sampling years used for the reconstruction. The number of

1-y-old geoduck in each year was calculated as a weighted mean of the multiple estimates:

$$R_y = \frac{\sum_t R_{t,y} \times W_{t,y}}{\sum_t W_{t,y}} \quad (12)$$

where $R_{t,y}$ is the estimated number of 1-y-old geoduck in year y based on the bio-samples collected in year t , and $W_{t,y}$ is the weight defined to be negatively correlated with the time interval between y and t :

$$W_{t,y} = \frac{1}{t - y + 1}$$

Simulations were conducted to generate confidence intervals for the estimates. Age compositions of the bio-samples, population densities in the bio-sampling years, and β of the vulnerability model were randomly regenerated in the way as described. In addition, M was also randomly regenerated from a normal distribution with the mean and standard error set to be the estimated ones using the Bayesian method with bootstrap of the age composition. The calculations were repeated for each set of regenerated data. A total of 999 data sets was regenerated, resulting in 1000 sets of population reconstructions.

RESULTS

Vulnerability

The parameter, β , in the vulnerability model (Eq. 1) was estimated to be 0.357 (0.124 SE) or 0.144 (0.099 SE) when age 6-y or 7-y geoduck, respectively, were assumed to be fully vulnerable to the fishery.

Natural Mortality

Estimated variations in M by the Monte Carlo method or the Bayesian method for different plots in Ritchie Bay appeared to be similar (Table 1). Geoduck in Plot 1 and 2 had the highest and lowest M , respectively, and geoduck in Plot 4 had a higher M than those in Plot 3. Estimated overall mean M was slightly higher using the Monte Carlo method than that using the Bayesian method (see Table 1). The overall mean M estimate was 0.039 (11.8% coefficient of variation, CV) using the Monte Carlo method, and 0.036 (7.5% CV) using the Bayesian method with bootstrap of the age composition. The estimated mean values of M were almost identical, whether bootstrap was applied on the age composition or not. Variances of M values were higher with the bootstrapping than without the bootstrapping.

Values of M for geoduck in Marina Island could not be reliably estimated. Using the Monte Carlo method, the estimated mean M was 0.06 for Plot 1, but the SE was 0.033 with a CV of 53.3% (see Table 1). For Plot 2, estimated M values were negative in approximately 50% of the simulations. For Plot 3, estimated M values were negative in all the simulations.

Recruitment

The general patterns of recruitment rates were similar among individual beds in Ritchie Bay, whether the estimated M for individual beds or overall mean M was used. Therefore, we only reported our findings using the overall mean M .

During the 10 y before the experiment and in the 1st experimental year of 1991 at Ritchie Bay, recruitment rates were similar among the four plots (Fig. 1, Fig. 2). Within the 3 y after the beginning of the experiment (during 1992 to 1994), there seemed to be high recruitment in Ritchie Bay, with the highest occurring in Plot 1, and recruitment was higher in Plots 2 and 4 than in Plot 3 (see Figs. 1, 2). Within the 4 to 8 y after the beginning of the experiment (during 1995–1998), recruitment appeared to be low relative to the period of 1992–1994, with recruitment almost identical among the four plots (see Figs. 1, 2).

During the 10 y before the experiment and in the 1st experimental year of 1992 at Marina Island, recruitment was, in general, the highest in Plot 3 and the lowest in Plot 1 (Fig. 3, Fig. 4). Within the 3 y after the beginning of the experiment (during 1993–1995), recruitment in Marina Island appeared to be strong, but still the highest in Plot 3 and the lowest in Plot 1 (see Figs. 3, 4). Within the 4 to 8 y after the beginning of the experiment (during 1996–1999), recruitment seemed to have generally decreased somewhat from the relatively strong recruitment during 1993 to 1995, but the pattern of recruitment did not seem to have changed. Plot 3 still had the highest recruitment, and recruitment was higher in Plot 2 than Plot 1 (see Figs. 3, 4).

Geoduck recruitment rates were approximately 13 or 14 times higher in the experimental plots of Ritchie Bay than those of Marina Island. The mean densities of 1-y-old geoduck, over all years and plots, were 0.22 per m² in Ritchie Bay and 0.016 per m² for Marina Island.

DISCUSSION

Natural mortality rate (M) is a crucial biologic parameter for understanding geoduck population dynamics. Bradbury and Tagart (2000) found that their yield modeling was most sensitive to the estimates of geoduck natural mortality, and recommended that greater effort be spent on making more reliable estimates of M . We

used a new method to estimate M for geoduck by using age structure modeling, and taking advantage of the time series of density and biosample age frequency data. We included a vulnerability model so that abundance of young geoduck that were not fully vulnerable to divers, could be estimated and included in the comparison of model-derived abundances with survey-derived abundances. Our method was not affected by variation in recruitment, but relied on the accuracy of abundance estimates based on the surveys. In contrast, three other methods have been used in the

estimation of M for geoduck populations. The first and most commonly used method was the catch curve analysis of a range of age frequency distributions selected ad hoc. Values of M for geoduck estimated in this way ranged from 0.01 to 0.04 (Bradbury & Tagart 2000, Breen & Shields 1983, Harbo et al. 1983, Sloan & Robinson 1984, Noakes 1992, Noakes & Campbell 1992). This method is based on the assumption that recruitment is constant over the age range being analyzed, and a shift in recruitment would bias the estimates of M (Ricker 1975, Bradbury & Tagart 2000). There is evidence that geoduck recruitment was low in recent years relative to those in the 1930s (Orensanz et al. 2000). To overcome the impact of temporal variations in recruitment on M estimation, Orensanz et al. (2000) used a second method to analyze age frequency distribution of dead geoduck shells found within the sediments. They estimated M to be 0.036, which was within the reported range of M for geoduck. The third method of estimating M was to trace the fate of individuals *in situ* within a time frame. Bradbury et al. (2000) estimated M to be 0.016 based on the dead proportion of geoduck marked by thin plastic stakes next to the siphons in an unfished site a year earlier. This latter estimate of M was in the low part of the reported range.

The method of this study estimated an overall M for geoduck at Ritchie Bay of 0.036 to 0.039, which was in the upper part of the range reported by previous studies using the first two methods (see earlier). The catch curve analysis of previous studies relied mainly on relatively old geoduck, as few small geoduck were caught and the low cut-off age was usually set to be the age fully vulnerable

Figure 2. Average (dots) and range (vertical lines) of mean geoduck 1-y-old densities in three different periods in each experimental plot at Ritchie Bay.

to fishing. The method of tracing the fate of tagged individuals used geoduck $>3-4$ y (Bradbury et al. 2000). If young geoduck suffer from a higher mortality rate, the previous methods would tend to result in estimates of M that would be somewhat lower than our method, which accounts for young geoduck.

We assessed the variations in estimated M using Monte Carlo Simulations and the Bayesian method. Ideally, ages of bio-samples should be treated as parameters and sequentially sampled in the application of the Gibbs sampler to produce a new set of age structure in each circle of random samplings. However, we did not know the standard errors for age determinations for individual samples. For an approximation, we used bootstrapping to regenerate new sets of age structures. The estimated mean value of M for

Figure 4. Average (dot) and range (vertical line) of mean geoduck 1-y-old densities in three different periods in each experimental plot at Marina Island.

each plot at Ritchie Bay was almost identical using both techniques, whether bootstrapping was applied or not, although the variances were, expectedly, larger with than without applying the bootstrap method.

Geoduck natural mortality was difficult to estimate from the Marina Island experimental plots using the available time series data. The estimated mean density of geoduck population in Plot 3 increased from 0.03 m^{-2} in 1996 to 0.182 m^{-2} in 2001 based on the surveys (see Fig. 1 of Campbell et al. 2004). The average annual increase in density is 0.0370 m^{-2} , whereas densities of age 7-y geoduck in Plot 3 were estimated to be 0.028 in 1992 and 0.03 in 2001 (See Table 4 of Campbell et al. 2004). The apparent increase in population size in this plot could not be fully contributed by recruitment. Thus, M for Plot 3 could not be meaningfully estimated using the age-structure model. Similarly for Plot 2 at Marina Island, in approximately 50% of the simulations, increases in population size were higher than increases in recruitment. Consequently, the model estimated negative values of M to account for the increases in population size.

To have an effective fishing strategy, one not only needs to know M , but also require an understanding of the impact fishing and population size or density on subsequent recruitment. Bureau et al. (2002) reported that recruitment in recent years appeared to be strong in a number of beds with relatively long harvest histories, suggesting that harvest did not have a negative effect on recruitment. Goodwin and Shaul (1984) found that harvested sites had fewer recruits than the unharvested controls in Port Gamble and Treble Point in Puget Sound, suggesting possible adverse impact of fishing on subsequent recruitment. However, their experiments could not conclusively demonstrate an adverse effect, because the differences were not significant due to the low number of recruits. Unlike our experiments lasting 9 y, the experiment by Goodwin and Shaul (1984) lasted for about 20 mo, which allowed only one geoduck setting season to be observed and the young-of-the-year to grow to the size large enough to be retained by the venturi sampler. Thus, their study could only indicate the possible short-term adverse impacts of fishing on recruitment.

One of the obvious reasons for possible adverse impact of fishing on recruitment was the disturbance of sediment caused by digging into the sediment beside the siphons of geoduck during the fishing (Orensanz et al. 2000). Fishing activity appeared to be highly disruptive of the substrate (Breen & Shields 1983), which

could affect geoduck larval settlement and increase the mortality of newly settled juveniles. We examined and compared geoduck 1-y-old densities that were used as a proxy for relative larval settlement and an index for recruitment of geoduck to the fishery 5 or 6 y later at age 6 or 7 y.

Our study on the impact of harvesting provided new information on recruitment. Recruitment of 1-y-old geoduck during the years before the experiment in Ritchie Bay appeared to be similar among the four experimental plots, suggesting that some physical factors, such as hydrodynamics, or biologic factors, such as predation, played a similar role in larval settlement and or juvenile survival between the four experimental plots. Within the first 3 y (1992–1994) after the beginning of the experiment at Ritchie Bay recruitment appeared to be high. After 62% harvested at the beginning of the experiment in 1991, Plot 1 had a higher recruitment than the two unharvested plots 2 and 4 during 1992 to 1994. The high recruitment in Plots 1 and 2 during 1992 was likely, to some extent, due to artificial seeding of hatchery reared juveniles in 1991 (Campbell et al. 2004). In contrast, Plot 3 had the lowest recruitment during 1992 to 1994, whereas high exploitation occurred during 1991 to 1993 with almost all large geoduck being removed, suggesting that severe harvest might have negatively affected recruitment in the short term (≤ 3 y). Possible short-term negative impacts have also been reported by Goodwin and Shaul (1984). Recruitment rates appeared to be similar again among the four plots 4 y after the beginning of the experiment (i.e., after 1994), offering no evidence that heavy harvesting either positively or negatively affected recruitment in Ritchie Bay in the long-term (> 3 y).

In contrast to Ritchie Bay, Marina Island geoduck recruitment was the highest in Plot 3 and the lowest in Plot 1 during the 10 y before the experiment and the 1st experimental year, suggesting that hydrodynamics was likely affecting larval settlement differently between the three experimental plots. Within the first 3 y (1993–1995) after the beginning of the experiment, the general

differences in recruitment rates among the three plots remained the same as before. The lowest recruitment occurred in the unharvested Plot 1. Despite a heavy 3-y harvest, with almost all geoduck removed during 1992–1994, Plot 3 had better recruitment than either moderately harvested Plot 2 or non-harvested Plot 1 during 1993 to 1995. This pattern of recruitment was also observed 4 y after the beginning of the experiment. The impact of harvesting, if there was any, was probably largely masked by physical factors such as the local hydrodynamics differentially providing different larval settlement supply. Other factors, such as predation also may have affected post settlement survival. We concluded that at Marina Island low geoduck densities throughout the 9-y experiment could provide little evidence of either positive or negative impact of fishing on recruitment.

The age-structure model was a useful tool for estimating historical recruitment patterns and M in individual geoduck beds. The value of M estimated by the age-structure model was likely to be more accurate than estimated by the method of catch curve analysis of age frequency distributions, because the age-structured model takes into account the temporal variations in recruitment and young geoduck not fully vulnerable to fishing. The constant recruitment assumption, required of the method of catch curve analysis, is unlikely to be an accurate assumption especially for the long-lived geoduck. Also, an age range has to be chosen for the catch curve analysis, and selection of different age ranges is likely to result in different M values. Use of the age-structure model, however, requires surveys for density and biosamples for age frequencies in the same beds over multiple year intervals, which could be achieved through long term planning for fisheries assessment purposes.

POPULATION ABUNDANCE ESTIMATES OF THE NEW ZEALAND GEODUCK CLAM, *PANOPEA ZELANDICA*, USING NORTH AMERICAN METHODOLOGY: IS THE TECHNOLOGY TRANSFERABLE?

PAUL EDWARD GRIBBEN,^{1*} JEREMY HELSON² AND RUSSELL MILLAR³

¹School of Environmental and Marine Sciences, and Leigh Marine Laboratory, University of Auckland, Private Bag 92019, Auckland, New Zealand; ²Island Bay Marine Laboratory, School of Biological Sciences, Victoria University of Wellington, PO Box 600, Wellington, New Zealand; ³Department of Statistics, University of Auckland, Private Bag 92019, Auckland, New Zealand

ABSTRACT This study investigates the applicability of methods used to describe patterns of distribution, and estimates of density and biomass of the Pacific geoduck clam, *Panopea abrupta*, from western North America for populations of the New Zealand geoduck, *Panopea zelandica* in Kennedy Bay, on the Coromandel Peninsula, and in Wellington Harbour. Central to this is the use of line transect surveys and estimations of the detection rate of geoduck (show-factor) using counts of siphon holes. Studies were restricted to less than 17 m water depth. Geoduck in Kennedy Bay were found from 4–8 m water depth, whereas geoduck in Wellington Harbour occurred in several separate beds from 4–16 m. In Wellington Harbour, there was a pattern of increasing numbers with depth up to ~15 m. Numbers seemed to decrease thereafter. Analysis of sediment samples indicated that *P. zelandica* was more prevalent in fine sand to fine silty sand substrates. *P. abrupta* is found in similar habitats. There was no significant difference in the show-factor (the proportion of geoduck detectable by sight or touch vs. the actual number of geoduck present) of geoduck with respect to season (summer and winter), region (Wellington Harbour and Kennedy Bay), or tidal height (low, mid, and high tide). Hence, a mean show-factor of 0.914 was used to adjust density estimates from all surveyed populations. Estimates of the mean population density (\pm SE) of *P. zelandica* were much lower than those reported for *P. abrupta* ranging from 0.058 (\pm 0.01) geoduck/m² in Kennedy Bay to 0.489 (\pm 0.08) geoduck/m² in Shelly Bay, Wellington Harbour. Survey densities, abundance, and biomass estimates were reasonably well determined with coefficients of variation (CVs) generally less than 20%. The results suggest that the methods used to provide population estimates for *P. abrupta* are readily transferable to *P. zelandica*. However, further research needs to be conducted on the diver variability on counts of geoduck, the role that geoduck occurring in water depths >17 m play in the population dynamics of local populations, and the density dependence of fertilization success of *P. zelandica*. Given the low estimates of density in this study, fisheries managers will have to carefully consider the feasibility of sustainably harvesting this species.

INTRODUCTION

Geoduck are one of the largest and longest-lived clams in the world (Beattie & Blake 1999). The Pacific geoduck clam, *Panopea abrupta* (Conrad 1899) (= *generosa*), from western North America can reach ages in excess 100 years (Goodwin & Shaul 1984, Sloan & Robinson 1984) and individuals as large as 3.25 kg have been recorded (Goodwin & Pease 1991). The only other species for which detailed biological information is available is the New Zealand geoduck, *Panopea zelandica* (Quoy & Gaimard 1835). Although not as large as *P. abrupta*, individual *P. zelandica* can reach 600 g and 80 years of age (Gribben & Creese, in press).

Commercial harvesting of *P. abrupta* forms the most important clam fishery on the Pacific Coast of North America. Large numbers are found in Puget Sound, Washington, and British Columbia, where subtidal stocks have been exploited since the 1970s. The combined Washington and British Columbian fisheries are worth US\$35 million annually (Harbo 1998, Hoffman et al. 2000). A small fishery established in 1988 for *P. zelandica* was closed in the early 1990s pending its introduction into the quota management system (QMS) (Breen 1994). Recently, there has been renewed interest in establishing commercial fisheries and aquaculture industries because of the similarity of *P. zelandica* to *P. abrupta*.

Fisheries for *P. abrupta* are based on detailed habitat descriptions and established methods for providing accurate density and biomass estimates (Hand & Dovey 1999, 2000). Geoduck density is estimated by counting the number of siphon holes visible at the

sediment surface. However, this can lead to an underestimation of the number of geoduck present as not all geoduck show at the same time (Goodwin 1977, Hand & Dovey 1999). Central to obtaining accurate density estimates is the use of show-factors. The show-factor is the proportion of geoduck that is visible or can be felt below the sediment surface versus the total number present in control plots. Any estimates of geoduck density obtained using diver transects are then adjusted by the appropriate show-factor. These have been shown to vary seasonally (Goodwin 1977), tidally (Hand & Dovey 1999) and with storms (Campbell et al. 1996a).

Most of the current literature available for *P. zelandica* concerns estimates of age, growth and mortality (e.g., Breen et al. 1991, Gribben & Creese, in press), as well as descriptions of larval (Gribben & Hay 2003) and sexual development (Gribben & Creese 2003, Gribben et al. 2004). *Panopea zelandica* is known to occur throughout New Zealand's three main islands in subtidal sand and mud habitats (Morton & Miller 1973, Powell 1979). However, the distribution and general habitat preference of local populations remains poorly described. Moreover, the applicability of methods used to provide reliable density and biomass estimates for *P. abrupta* is also yet to be investigated. Understanding the environmental requirements and providing realistic estimates of the density for local populations will be the first step in developing sustainable management policies and for assessing the suitability of *P. zelandica* for culture (Malouf & Bricelj 1989, Murawski & Serchuk 1989).

This study describes the distribution and general habitat preference (i.e., sediment type and water depth) of populations occurring in Kennedy Bay, on the Coromandel Peninsula, and Well-

*Corresponding author. E-mail: p.gribben@unsw.edu.au

ton Harbour, and also investigates the show-factors of *P. zelandica* occurring in these same populations. It also determines whether established methods of providing density estimates for *P. abrupta* (i.e., counts of siphon holes using diver transect surveys) are readily transferable to *P. zelandica*, and whether they can be used reliably to provide further population abundance/biomass estimates.

METHODS

The harvestable biomass of *P. abrupta* is considered to be only that part of the population that occurs in waters shallower than 17 m below chart datum. This is due to the risks posed to divers spending considerable lengths of time underwater at depths greater than this. Thus all research in this study was conducted in waters no deeper than 17 m.

Relationship Between Gross Environmental Characteristics and Distribution

Transect surveys were used to determine the distribution and sediment characteristics of local *P. zelandica* populations occurring in Kennedy Bay, on the Coromandel Peninsula, and Shelly Bay, in Wellington Harbour (Fig. 1A to C). Similar methodologies were used for describing the distribution of local *P. abrupta* populations in North America (Hand & Dovey 1999, 2000).

Kennedy Bay is a large circular, sheltered bay 1.5 km in diameter, which is shallow and gently sloping with a maximum depth of 11 m at the bay entrance. Kennedy Bay is generally only

exposed to winds from the north-northeast. Shelly Bay, a small sheltered embayment located within Wellington Harbour, is more sheltered, although steeper in slope, than Kennedy Bay and can reach depths of 20 m within 60 m of the sea shore.

In Kennedy Bay, five transects 1400 m long and 250 m apart (designed to encompass the majority of the subtidal area of the bay) were sampled from Sept 29 to Oct 1, 1999. Eight stations 200 m apart (as determined by DGPS prior to the beginning of the survey) were sampled along each transect. The number of geoduck in $16 \times 1\text{-m}^2$ quadrats was determined at each sample station. The large number of quadrats searched reflected the low density of geoduck found in this bay observed from previous exploratory studies (Gribben unpubl. data). Sediment samples were collected at all stations using a hand held corer. Approximately 600 g of sediment was extracted for analysis at each station using a corer 5 cm in diameter pushed a depth of 100 mm into the sediment. In Shelly Bay, five transects 50 m apart (determined by running a tape measure parallel to the shoreline) were sampled from Oct 26 to 28, 1999. Transects started at the 5 m depth contour, except for the first transect which began at the 2.5 m depth contour. Sediment samples were collected every 15 m along a tape measure run perpendicular to the shore. Transects ranged in length from 75–120 m, with $4 \times 1\text{-m}^2$ quadrats searched for geoduck at each station. Lower numbers of quadrats were used in this survey because geoduck were much more abundant in this area (Gribben unpubl. data). Each transect ended between the 13–16-m depth contours depending on when the sediment became too silty, making it difficult to effectively search quadrats for geoduck. All sediment samples collected from Kennedy Bay and Shelly Bay were put in labeled plastic bags and transported back to the Leigh Marine Laboratory where they were dried in an oven at 60 °C for 3 days. Samples were sieved using a vibrating shaker through a graded series of seven sieves: mesh sizes <125 μm , 125 μm , 250 μm , 500 μm , 1 mm, 2 mm, and 4 mm (Wentworth grade classification) (Ingham 1971). Median phi size was calculated for each sample as per the methods outlined in Buchanan (1984). The results are displayed as bubble plots of geoduck density versus water depth and median phi size for both populations (Sigma Plot, SPSS 2000).

Investigation of Show-Factors

The show-factor of *P. zelandica* was investigated in Shelly Bay and Mahunga Bay, Wellington Harbour, and in Kennedy Bay (Fig. 1). The general methods are as follows. Depending on the experiment (see below), a number of semipermanent quadrats were placed in each population in areas of known high density (as determined from the survey above) to increase precision. Each quadrat was visited for 5 consecutive days. The first time a quadrat was visited the geoduck present (those whose siphons could be felt or seen) were recorded and staked. On subsequent visits any geoduck not previously recorded were also counted and staked. Estimation of show-factor proportions follows the methods outlined in Hand and Dovey (1999). The proportion showing on any day, SP_i , in any given quadrat is calculated as

$$SP_i = X_i / \sum_i T \quad (1)$$

where X_i is the number of geoduck showing on day i and T is the total number of geoduck observed, assuming that no geoduck remained hidden for more than 5 consecutive days (justification for

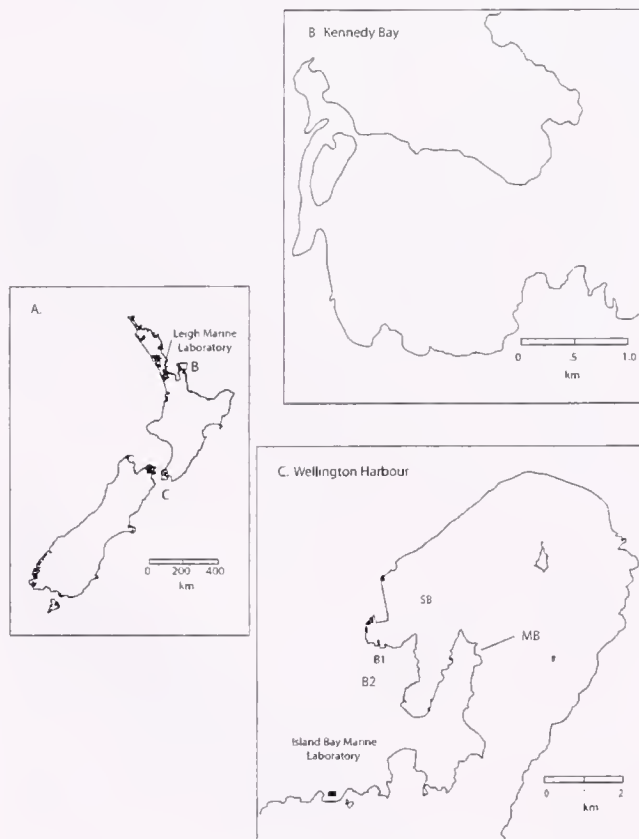

Figure 1. Map of New Zealand (A) indicating the position of study sites in Kennedy Bay (B), and Wellington Harbour (C), including Shelly Bay (SB), Mahunga Bay (MB), Bay 1 (B1) and Bay 2 (B2).

this is given in the discussion). The standard error of the estimate ($se(SP_i)$) is approximated by

$$se(SP_i) = \sqrt{\frac{(SP_i(1 - SP_{it}))}{\sum T}} \quad (2)$$

because SP_i is binomially distributed.

Two studies were conducted in Mahunga Bay and Shelly Bay, in Wellington Harbour. The first study investigated the show-factor of geoduck at different tidal heights (slack low tide and slack high tide), seasons (summer and winter) and sites (Mahunga Bay and Shelly Bay). The winter survey was conducted from June 26 to July 1, 1999, and the summer survey from Jan 29 to Feb 4, 2000. Five replicate 4 m² quadrats per treatment were placed in areas of high density within each population. The second study, conducted from Oct 17 to 21, 2000, investigated whether the show-factors at the two sites differed between slack tide or mid tide: there was no seasonal component to this experiment. However, the quadrats used in the first study were too large to search efficiently because disturbed sediment obscured the search for geoduck before the quadrat was completely searched. Instead, 10 × 1-m² quadrats were used for each treatment combination at each site.

In Kennedy Bay, studies one and two, described above, were combined. The effect of tidal flow (slack low, slack high, and mid tide) and season on show-factors was investigated in summer from Jan 19 to 23, 2001 and in winter from July 23 to 27, 2001. Thirteen replicate 1 m² quadrats were used for each treatment combination. The show-factors were modeled as binomial proportions using logistic regression (PROC Logit, SAS 1988) to investigate whether they were influenced by tidal flow, season or location.

Population Estimates

Estimates of area, density, abundance, and biomass of geoduck populations in Kennedy Bay, Shelly Bay, and Mahunga Bay were provided once the initial distribution surveys had been conducted. Surveys of population estimates in Wellington Harbour were extended to include 2 bays immediately to the south of Shelly Bay, hereafter referred to as Bay 1 and Bay 2 (Fig. 1A to C).

In the Wellington Harbour sites, transects (20 m apart) of a known length and width (1 m) were placed in each population to provide area and density estimates. Although the transects were spaced at regular intervals, the first transect was placed randomly at the either northern or southern perimeter of the bay. This effectively renders all transects random. All transects began at 6 m below chart datum and ran to 15 m. The length of each transect was recorded with a tape measure. All geoduck encountered along the tape measure within the bounds of a 1-m stick centered on tape measure were recorded. A total of 11 transects were run in Mahunga Bay, 10 transects in Shelly Bay, 6 transects in Bay 1, and 10 transects in Bay 2. In Kennedy Bay, a total of 14 transects, 600 m long and ~60 m apart were run through the population as defined in the initial survey. The starting point for each transect was determined by DGPS prior to the beginning of the survey. Again, although the transects were regularly spaced, the accuracy with which this could be done effectively renders the transects random (Hand et al. 1998a).

Area Estimates

Estimates of area follow the methods outlined in Hand and Dovey (1999). The surveyable area in each bay was defined to be

the sum of the area of all the possible transects. Because transect length was only known for those sampled, the length of transects not sampled was assumed to be equal to the length of the nearest sampled transect (Hand & Dovey 1999). Thus, the surveyable area A (m²) is

$$A_j = \sum_{i=1}^n L_i(W1_i + W2_i) \quad (3)$$

where n is the number of transects sampled in bed j , L_i is the length (m) of the i^{th} transect, and $W1_i$ and $W2_i$ are the distances (m) on either side of the transect i , equidistant to its adjacent transect. That is, as transects are 20 m apart in Wellington Harbour and 60 m in Kennedy Bay, both $W1_i$ and $W2_i$ are 10 m in Wellington Harbour and 30 m in Kennedy Bay.

Density Estimates

A common show-factor was assumed for all transects within a bed. Estimates of mean geoduck densities were obtained by estimating the mean density of observed geoduck over a bed, and then adjusting for the show-factor. The mean density of geoduck observed in a bed, o_j , was estimated using the ratio estimator method because it reduces the variance of the estimate arising due to unequal transect lengths by weighting the transect counts according to the transect length (Hand & Dovey 1999). This gives

$$o_j = \frac{\sum_{i=1}^n b_i}{\sum_{i=1}^n a_i} \quad (4)$$

where b_i is number of geoduck found along a transect and a_i is the total area of transect i in square meters. The standard error of o_j is given by

$$se(o_j) = \sqrt{\frac{\sum_{i=1}^n (b_i - o_j a_i)^2}{n(n-1)\bar{a}^2}} \quad (5)$$

where

$$\bar{a} = \frac{1}{n} \sum_{i=1}^n a_i$$

is the average area of the transects (Campbell et al. 1998a, Hand & Dovey 1999).

Adjusting for the show-factor gives the estimate of mean adjusted geoduck density (d_j) is

$$d_j = o_j / SP \quad (6)$$

where SP is the estimated show-factor (Campbell et al. 1998a, Hand & Dovey 1999). The estimation variability of SP needs to be considered when calculating the standard error of d_j . This is done using the formula

$$se(d_j) = \quad (7)$$

after Thompson (1992).

Population Density and Biomass Estimates

Estimates of total numbers (± 1 SE) of geoduck in each bed were calculated from the estimates of mean density (m⁻²) and total surveyed area of each population. Total biomass (± 1 SE) of geo-

duck in each population was determined from estimates of total abundance and mean whole wet weight (± 1 SE).

Estimates of mean whole wet weight (g) (± 1 SE) of geoduck in Kennedy Bay and Wellington Harbour were determined by haphazardly collecting geoduck by SCUBA Kennedy Bay ($n = 153$) during January 1999 and from Shelly Bay ($n = 113$) during June 1999. Whole wet weight was measured to the nearest 0.1 g, using a Mettler electronic balance for all individuals. All clams were processed within 15 minutes of capture. The mean whole wet weight from Shelly Bay was assumed to be representative of all bays in Wellington Harbour. The standard error of the product of mean weight (W) and total abundance (N) was estimated by the equation

$$S.E.(NW) = \sqrt{W^2 s_N^2 + N^2 s_W^2} \quad (8)$$

as given in Topping (1962).

RESULTS

Environmental Characteristics

The mean density of geoduck ranged from 0 to 3.5 geoduck/m² at stations sampled in Shelly Bay, and from 0 to 0.44 geoduck/m² for stations sampled in Kennedy Bay (Fig. 2). Geoduck in Shelly Bay were found between 4–16 m below sea level, although few geoduck were found in water shallower than 6 m and deeper than 15 m. It is noted that few stations deeper than 15 m were sampled. Geoduck were not evenly distributed throughout their depth range and appeared to be clumped into 2 main areas, one between 6–8 m below sea level and another between 10–15 m. The low number of geoduck from 8–10 m corresponds with an area that has larger amounts of shell on the surface of the sediment, which runs through this bay at these depths (Gribben pers. obs.). The distribution of geoduck in Kennedy Bay was mostly confined to an area approximately 1000 \times 600 m (Fig. 3). The depth range (~3.5 to 8 m) of geoduck in Kennedy Bay was more restricted than that in Shelly Bay (Fig. 2).

Median phi size in Shelly Bay was variable, ranging from minus 3 to 2.8 (large stones to sand-silt sediments). The narrower

Figure 2. Plot of geoduck density (m⁻²) in relation to Phi size and water depth in Kennedy Bay (black circles) and Shelly Bay (clear circles). Circles are mean density of geoduck sampled at each station. Smallest circles = no geoduck, median circles = 1.75 m⁻² and largest circles = 3.5 m⁻².

range of phi sizes in Kennedy Bay, 1.0 to 2.9 (sand to fine sand sediments) reflected the more homogenous nature of sediments in this area (Fig. 2). Geoduck in Shelly Bay were only found in sediments with a median phi size between 1.8 and 2.5 (fine sand to silty fine sand sediments) (Fig. 2). No geoduck were found in sediments coarser than <1.8. Geoduck in Kennedy Bay were not found in sediments coarser than 2.5, although few stations were of that type. This study ignored any patterns of abundance that may have existed for geoduck in Shelly Bay occurring in waters deeper than 16 m.

Show-factors

The mean proportions (\pm SE) of geoduck showing in Wellington Harbour and Kennedy Bay are summarized in Figures 4 and 5 respectively. In Wellington Harbour, few new geoduck were observed after day 3 in experiment 1 (Fig. 4A,B), whereas no new geoduck were found after day 2 in experiment 2 (Fig. 4C). The change of experimental design seems justified because the proportions of geoduck found on the first visit were significantly higher ($P < 0.005$) in experiment 2 compared with experiment 1. No new geoduck were found in Kennedy Bay after day 2 (Fig. 5).

The absence of any significant differences in show-factors within either region allowed investigation of possible differences that may have existed between Kennedy Bay and Wellington Harbour. The Kennedy Bay pooled data set was tested against a Wellington data set containing only the pooled data (including both Mahunga Bay and Shelly Bay) from experiment 2, as it followed the same methodology as that in Kennedy Bay. There was no significant difference in the show-factor between the two data sets ($P = 0.99$). As a consequence, a show-factor of 0.914 (± 0.019), estimated from the combined Wellington Harbour and Kennedy Bay data sets, was used to adjust total geoduck found and density, abundance, and biomass estimates from both regions (see below). The standard error of the total number of geoduck encountered for each transect was provided by equation 7 (see earlier).

Population Estimates

Mean transect density of geoduck in Kennedy Bay ranged from 0.01 to 0.13 geoduck/m², and in Wellington Harbour ranged from 0.04 to 1.14 geoduck/m² (Table 1). Geoduck were found on all transects sampled in all populations except for transects 5 to 10 in Bay 2. Thus, estimates of area, abundance, density, and biomass for this bay were determined for the first four transects only. Also, because of the very low number of geoduck found along transects 12 to 14 in Kennedy Bay, they were considered to be outside the bounds of the main population and were excluded from further analyses.

The population of geoduck in Kennedy Bay occupied the largest area (39.6 ha) of all of the five bays sampled (Table 2). Mean geoduck density was highest in Shelly Bay and lowest in Mahunga Bay. Kennedy Bay had the highest estimated abundance and biomass of geoduck and B1 the lowest, mainly due to the size of the area surveyed. Although Kennedy Bay was over an order of magnitude larger in terms of area than Shelly Bay, the overall biomass was only approximately 60% larger. This was a result of the lower mean density and smaller estimated weight found in Kennedy Bay.

DISCUSSION

There is considerable interest in developing fisheries and aquaculture industries for geoduck species throughout Asia and the

Figure 3. Contour plot of the distribution and density (not adjusted for show-factors) of geoduck (number m⁻²) in Kennedy Bay. Dashed lines indicate the main area of the bed used in subsequent analyses.

Pacific. Therefore, studies investigating the transferability of existing methodologies for determining population size and structure for *P. abrupta* from North America are both timely and necessary. This is the first study to describe the distribution, density and biomass of local populations of the New Zealand geoduck, *Panopea zelandica*, although this study was restricted to the harvestable population at <17 m water depth.

Morton and Miller (1973) and Powell (1979) described *P. zelandica* as an ocean beach mollusk found in sand and mud habitats throughout New Zealand. This study indicated that *P. zelandica* habitat range was more diverse than previously described. All the populations of *P. zelandica* investigated in this study occurred in sheltered bays indicative of more benign conditions, a habitat similar to that described for *P. abrupta* (Goodwin & Pease 1989). Other populations not investigated in this study occur at similar depths and environments (e.g., Golden Bay, Nelson, Gribben unpubl. data).

Studies have shown that the density of *P. abrupta* in Puget Sound, Washington, was higher in sand or mud-sand habitats than in mud, pea-gravel, or gravel substrates (Goodwin & Pease 1989). Other research has shown that density was positively correlated with water depth from 0–25 m, decreasing thereafter (Goodwin & Pease 1989, 1991; Campbell et al. 1996b). Similar results were

obtained for *P. zelandica* in this study. Although, our research only considered that part of the population that was harvestable, searches for geoduck at in silty sediments at depths greater >17 m indicated they were scarce (Gribben unpubl. data). However, the level to which geoduck found at greater depths contribute to the population dynamics of local populations is unknown and requires further investigation (Hand & Dovey 1999). Potentially, these harvest refugia could be an important source of larval recruits to the shallower fished stocks.

Although not quantified, observations suggested that geoduck in all bays appeared to be more abundant in areas that were covered in a film of benthic algae during spring and summer (Gribben unpubl. data). In Kennedy Bay, this region was in 5–6 m water depth and in the Wellington Harbour populations this occurred around 10–12 m. This may explain why geoduck in Kennedy Bay were mainly restricted to depths of 4–6 m when most of the bay appeared to have relatively homogenous sediments. The biofilms may provide a settlement cue for competent larvae as has been shown other marine bivalves (reviewed in Wicczorek & Todd 1998). Populations of *P. zelandica* spawn from spring to late summer so larvae would be in the water column and competent to settle during this period (Gribben et al. 2004). In a laboratory study, *P. zelandica* were shown to have a larval development

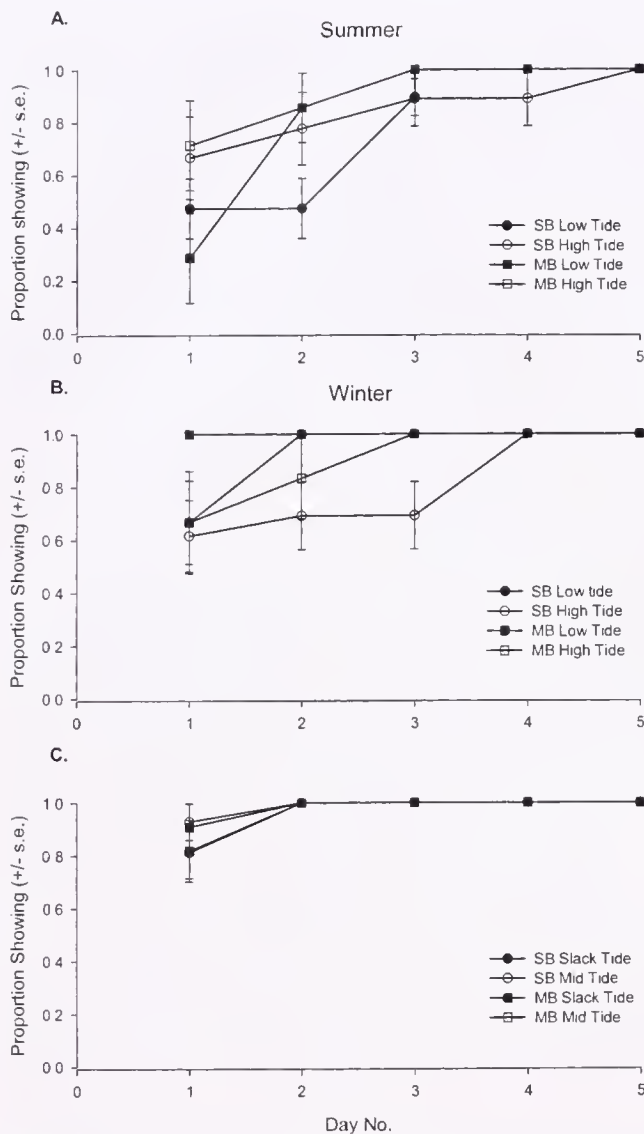

Figure 4. Cumulative proportion (\pm SE) of geoduck showing in show-factor plots in Shelly Bay (SB) and Mahunga Bay (MB), Wellington, during experiment one conducted during summer (A) from 29/01/2000 to 4/02/2000, winter (B) from 26/06/1999 to 1/07/1999, and experiment two (C) from 17-21/10/2000. Means are dots and vertical lines are \pm 1SE.

period of 16 days when maintained in water of 17 °C (Gribben & Hay 2003). Further to this, in studies on the feeding ontogeny of newly settled geoduck, *P. abrupta* were found to have incomplete siphons and used their palps to pass sediment surface material into their mouths (King 1986). Thus benthic algal mats may also provide a potential food source newly settled geoduck.

The counting of geoduck siphons is preferable to removing samples from the substrate because of the depth to which they bury, as removing them from the sediment and replacing them can lead to high levels of mortality (Gribben & Creese, in press). However, individual geoduck siphons are not consistently visible throughout the day, season or year (Goodwin 1973, 1977; Fyfe 1984; Campbell et al. 1998b). Consequently, area and time specific show-factors are required to correct the density counts in British Columbia and Washington State. Mean show-factors for *P. ze-*

landica were consistently above 90% regardless of the season, site, and time of tide, suggesting that this value may be generally applicable. However, our calculation of show-factors is based on the assumption that all geoduck do not remain hidden for more than 5 days. We believe that this is a valid assumption for the following reasons. Many studies on *P. abrupta* consistently indicated high show-factors (>90%) during summer months (Fyfe 1984, Hand & Dovey 1999, 2000). On a smaller scale, Hand and Dovey (1999, 2000) visited show-factor plots of *P. abrupta* of known abundances for 8–9 consecutive days. Show-factors were high on any given day (71% to 100%), indicating that nearly all geoduck were showing each day of the survey. In our study, once found a geoduck was visible on all subsequent days. This indicates that only reason that geoduck were not located initially was due to poor visibility or they were inadvertently missed.

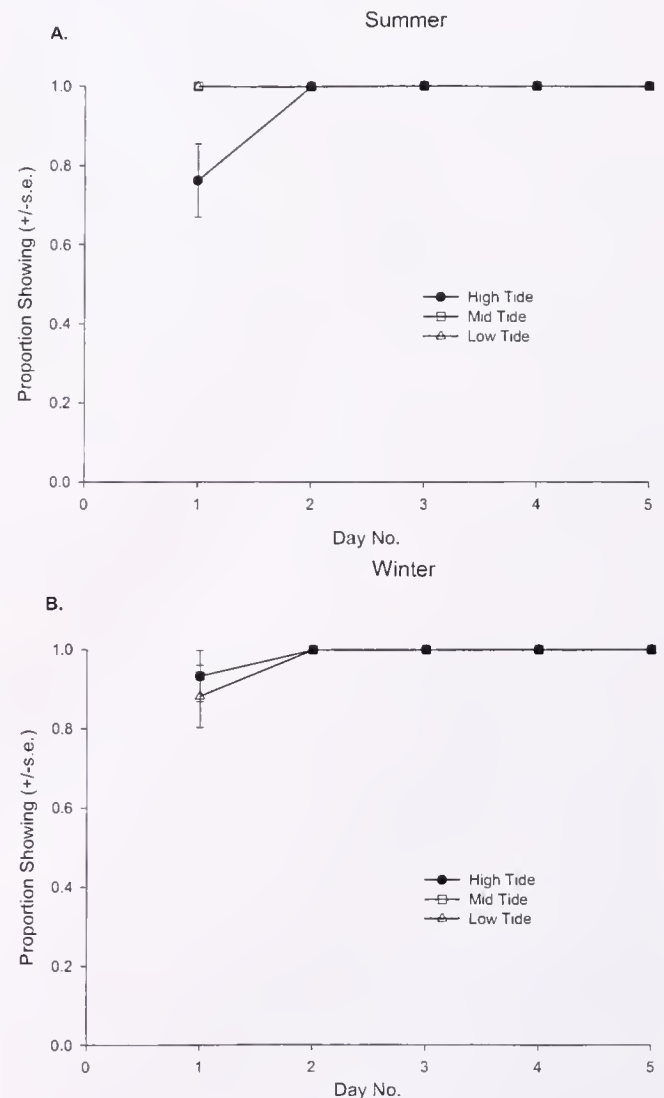

Figure 5. Cumulative proportion (\pm SE) of geoduck showing in show-factor plots in Kennedy Bay during summer (A) and winter (B) at high, mid, and low tides sampled from 26/6/1999 to 1/7/1999. Means are dots and vertical lines are \pm 1SE.

14	600	2								

Although several studies on *P. abrupta* have shown that show-factors are depressed during winter (Goodwin 1973, 1977; Fyfe 1984), winter is a period of active gametogenic development in populations of *P. zelandica* (Gribben et al. 2004). If *P. zelandica* were remaining inactive for extended periods of time, then it seems unlikely they could meet all metabolic needs, including gamete production during winter. Fyfe (1984), in a study of geoduck in Ritchie Bay, British Columbia, found that *P. abrupta* may lay "dormant" for periods of up to 2 months, possibly in response to low winter temperatures and food availability (Goodwin 1973, 1977; Fyfe 1984). However, the plots were only visited once a month during the winter period. Fyfe (1984) assumed that previously tagged geoduck not visible at the next sampling period had remained inactive for at least that period. This may certainly not have been the case. In fact, gametogenesis in *P. abrupta* from both Washington (Andersen 1971, Goodwin 1976, Beattie & Goodwin 1992) and British Columbia (Sloan & Robinson 1984) also progresses rapidly through autumn and winter. Hence, it would also seem unlikely that *P. abrupta* would remain inactive for extended periods.

This study indicated the benefit of using smaller sized quadrats when assessing show factors, as shown by the significant increase in show-factors between experiments 1 and 2 in Wellington Harbour. The smaller quadrats used in experiment 2 were easier and quicker to search. The poor show-factor and large confidence intervals in experiment 1 were due to the large size (2 m × 2 m) of the quadrats and the silty nature of the sediment. The time needed to search the quadrats increased the disturbance of the sediment making geoduck difficult to find. However, the 1-m² quadrats used in subsequent experiments could be further refined into narrow strip transects (approx. 1 m × 10 m), similar to those used in the North American surveys (e.g., Hand & Dovey 1999, 2000) that would allow increased numbers and a larger area to be surveyed.

In Puget Sound, a show-factor of 0.75 is currently used to adjust density estimates on all beds for refishing surveys unless a show plot is established (Bradbury et al. 2000). This is strictly a

management decision assumed to give a conservative estimate of harvestable biomass. The common 0.914 show-factor presented here suggests that this adjustment may be applicable to other populations of *P. zelandica*. However, more research needs to be conducted on the applicability of a general show-factor to other populations, especially those found in cooler waters. All geoduck counts in this study were conducted by a single experienced geoduck diver.

Density and Biomass Estimates

The setting of annual quotas for *P. abrupta* is reliant on reliable estimates of density and area, which vary geographically (Sloan 1985). Every parameter used in calculating virgin density, abundance, and biomass is estimated with varying uncertainty (Hand & Dovey 1999). Survey densities, abundance, and biomass estimates were reasonably well determined with coefficients of variation (CVs) of less than 20% except for the two smallest bays for which the CVs were approximately 30%. This may have been due to the small number of transects surveyed within the bounds of the populations. Increasing sample sizes (i.e., running more transects within the bays) may have helped reduce the CVs.

Estimates of the average densities of geoduck populations in British Columbia have ranged from 0.2 to 5.0 geoduck/m² (Breen & Shields 1983, Hand et al. 1998a, Hand et al. 1998b). Densities as high as 30 m⁻² have been recorded in Griffith Harbour, British Columbia (Hand & Dovey 2000). Average density based on 8589 transects in Puget Sound was 1.7 m⁻² and ranged from 0–22.5 geoduck/m² (Goodwin & Pease 1991). The mean population density estimates provided for *P. zelandica* in this study are lower than those estimated for the *P. abrupta* (Table 2). Although large in area, the low estimated density in Kennedy Bay would appear to make harvesting in this bay unsustainable. In Wellington Harbour, the mean density was much higher although the combined area of geoduck occupied in the regions surveyed was only ~5.5 ha. However, this is likely to be only a portion of the total population in the harbor, as many other bays with similar habitats to those surveyed were not explored. Geoduck will probably not be harvested from this harbor for reasons of pollution. Other larger populations are known to occur in the Marlborough Sounds, and Golden Bay, Nelson. Studies investigating the density, abundance and biomass of geoduck in this area are yet to be conducted.

Fisheries managers will have to be particularly careful in determining whether populations of *P. zelandica* can be harvested sustainably. Harvesting geoduck results in a thinning of the population, with the densest areas the most heavily fished. Evidence suggests that recruitment into North American geoduck populations has been falling for the past 20 years (Orensanz et al. 2000), although some several recruitment events have occurred in British Columbia in the last decade (Bureau et al. 2002). Because *P. zelandica* already occurs at low densities, harvesting may have a large effect on the potential fertilization success of geoduck. However, little is known of the density dependence of fertilization success for geoduck species and this warrants further investigation. Further to this, *P. zelandica* is protandric with females dominating the large size classes (Gribben & Creese 2003). Given that harvesting geoduck involves searching for siphon holes and the largest siphon holes generally contain the largest geoduck, harvesting may also target female geoduck resulting in populations that are egg-limited (Gribben & Creese 2003). This may have severe repercussions for future recruitment success.

TABLE 2.

Estimates of total area, show-factor (SF) adjusted total, mean density, total abundance, mean individual weight and biomass of geoduck found in all transects in each location.

KB, Kennedy Bay; SB, Shelly Bay; MB, Mahunga Bay; B1, Bay 1, and B2, Bay 2.
Standard error (\pm SE) given in parentheses.

The large differences in mean density and size of geoduck between the Kennedy Bay and Wellington populations may, in part, be due to large storm events that occurred in the Coromandel region in the mid 1990s, which saw large numbers of geoduck stranded on the beaches surrounding Kennedy Bay (George Potae, Kennedy Bay Mussel Company Ltd. pers. comm.). Since then, a large recruitment event occurred during 1997/1998 resulting in the population being dominated by two cohorts (Gribben et al. 2004). Geoduck in Shelly Bay were mainly large individuals with very few small geoduck present. Thus mean size and biomass in Kennedy Bay are unlikely to be static and will increase as the cohort develops. The future contribution that this smaller cohort will make to later biomass estimates is unknown because no reliable estimates of mortality are currently available for *P. zelandica* (Breen 1991, Gribben 2003).

The results presented in this study indicate that the methods used for describing the distribution, density, and biomass of populations of *P. abrupta* could be readily adopted for *P. zelandica*. However, less experienced searchers may have more difficulty in finding geoduck, especially when visibility is poor and during

winter months. During this period, geoduck were usually found by searching potential siphon holes, which is more time consuming. We recommend that abundance and biomass estimates not be conducted during winter or periods of poor visibility because less experienced divers may miss many geoduck leading to biomass underestimates, and that the variability in diver counts be investigated. Finally, before the sustainability of harvesting geoduck can be assessed further, work on the density dependence of fertilization success, recruitment, and natural mortality of *P. zelandica* must be conducted.

ACKNOWLEDGMENTS

The authors thank Robert Williamson, George Potae, and Andrew Bell for their assistance in collecting geoduck and Drs. Jonathan Gardner and Bob Wear for use of equipment. Thanks also to two reviewers, Drs. Alan Campbell and Wayne Hajas, for their helpful comments and suggestions on an earlier version of this manuscript. This study was supported by a Graduate Research in Industry Foundation scholarship, made possible with the help of the members of the Geoduck Research Group.

ABSTRACT The genetic population structure of geoduck clams (*Panopea abrupta*) in inland waters of Washington may affect fishery management and aquacultural practices involving this species. To investigate genetic differentiation in geoduck clams, samples were collected from 16 Washington State sites located in the five Puget Sound sub basins, southern Georgia Strait, and the Strait of Juan de Fuca. A collection from Clarence Strait in SE Alaska was included as an outgroup. Individuals were genotyped at 11 allozyme and 7 microsatellite loci. There was little differentiation overall, but the Freshwater Bay collection in the Strait of Juan de Fuca was differentiated from others at both microsatellite and allozyme loci. For both marker classes, there was no evidence of significant correlation between genetic and geographic distance measures. In contrast to the microsatellite loci, the allozyme loci were in Hardy-Weinberg Equilibrium (HWE). Deviations from HWE expectations at microsatellite loci were interpreted as being primarily due to primer-site sequence variation rather than population level processes such as inbreeding.

KEY WORDS: *Panopea abrupta*, geoduck, population genetics, larval dispersal

INTRODUCTION

Understanding the extent of gene flow provides insight into the demographic dynamics among natural populations. Generally, gene flow is correlated with dispersal ability in many organisms (Bohonak 1999), including many marine fishes and shellfishes (reviewed in Shaklee & Bentzen 1998). In sedentary marine bivalves, dispersal and gene flow occur only during the pelagic larval phase. Gene flow and larval dispersal may be correlated with spatial distribution in marine mollusks (Johnson et al. 2001); many investigators have failed to falsify the null hypothesis of panmixia at broad geographic scales in a variety of broadcast spawning marine species with pelagic larvae (e.g., *Crassostrea virginica* [McDonald et al. 1996]; *Littorina striata*, [De Wolf et al. 2000]; *Mytilus galloprovincialis* [Skalamera et al. 1999]). Nevertheless, some studies have demonstrated genetic structuring in a variety of marine invertebrate species with pelagic larvae (e.g., the American oyster, *Crassostrea virginica* [Reeb & Avise 1990]; *Ostrea edulis* [Launey et al. 2002]; the sea urchins *Strongylocentrotus purpuratus* [Edmands et al. 1996] and *S. franciscanus* [Moberg & Burton 2000]; and black abalone *Haliotis cracherodii* [Hamm & Burton 2000]). Examples of genetic differentiation on smaller geographic scales include the limpet *Siphonaria jeanae* (Johnson & Black 1984), the oyster *Crassostrea virginica* (Buroker 1983, [King et al. 1994]), cockles *Cerastoderma glaucum* (Mariani et al. 2002), and *Mytilus edulis* (Ridgway 2001). Most population genetic studies of marine invertebrates have focused on populations that are distributed along open coasts or island populations with discontinuous distributions separated by deep oceanic water. However, Parsons (1996) demonstrated significant genetic subdivision (9-locus F_{ST} = 0.16) over an area of only 75 km² in the intertidal gastropod, *Austrocochlea constricta*. Limited water movement in the area studied may have caused localized recruitment, resulting in the detected population differentiation (Parsons 1996).

The complex hydrology and bathymetry of Puget Sound in Washington State suggests the potential for restricted dispersal and population subdivision of marine invertebrates in the region. Puget Sound is a fjord-like estuarine system that is highly subdivided by numerous peninsulas, narrow passes, islands, and underwater sills (Fig. 1). It is comprised of five sub-basins oriented approximately along a north-south axis. At the north end is Admiralty Inlet, separated from the Strait of Juan de Fuca by a shallow sill. Admiralty Inlet connects to three long, narrow basins: from west to east these are Hood Canal, Main Basin, and Whidbey Basin. Southern Basin is connected at the south end of the Main Basin. Potentially important for larval dispersal, each basin is separated from its neighbor by a shallow sill, except for Whidbey Basin's constricted connection to the Main Basin (Ebbesmeyer et al. 1988). The Strait of Juan de Fuca, the sole connection of Puget Sound to the Pacific Ocean, is itself bounded by an inner and an outer sill, as well as the bathymetrically and hydrologically complex Georgia Strait to the north (Herlinveaux & Tully 1961). Collectively, these features restrict the flow of surface waters, leading to the possibility that the dispersal of pelagic larvae may be restricted, and hence that genetic differentiation of marine invertebrates might occur on relatively small geographic scales. On the other hand, Puget Sound's freshwater inputs and their typical estuarine surface outflow increase the propensity of passive surface particles to disperse in a seaward direction, and could be sufficient to genetically homogenize molluscan populations colonized by pelagic larvae drifting seaward from populations in inner inlets. In a study of marine bivalve population genetics in Puget Sound, Parker et al. (2003) recently found significant differences in allele frequencies among collections of the endemic *Prototheca staminea*, but no differences among collections of *Macoma balthica*.

One of the most fecund species with pelagic larvae in Puget Sound, Washington, the bivalve *Panopea abrupta*, or geoduck clam, is found there in high densities and is among the largest, longest-lived (> 100 y), and deepest burrowing clams known. It occurs from the low intertidal zone to a depth of 100 m, buried up

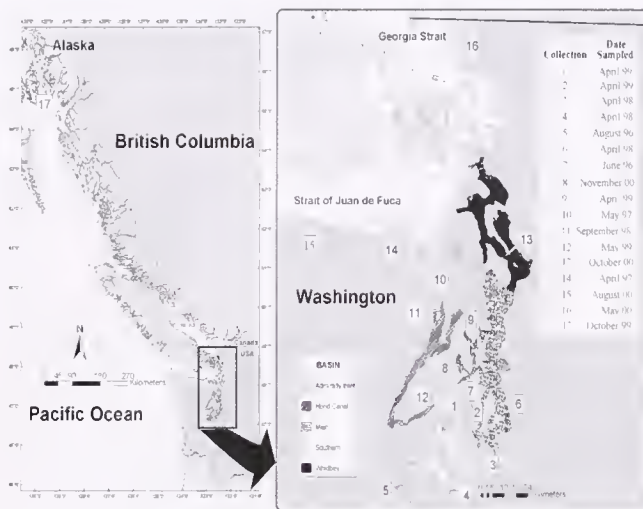

Figure 1. Puget Sound hydrographic basins, and sample dates and geographic locations for 17 geoduck clam (*Panopea abrupta*) collections from Washington and Southeast Alaska.

to 1 m in loose stable substrates in marine and estuarine environments from Alaska to Mexico (Goodwin & Pease 1989). Geoducks are dioecious synchronized broadcast spawners, with a pelagic larval phase that lasts from 3–6 weeks (Goodwin 1976). Experimental evidence indicates mean fecundities of 40 million eggs per year (Beattie 1992). A species may use the strategy of high fecundity to overcome the spatial and temporal odds of gamete union (Hedgecock 1994) and/or larval survival, or, secondarily, to maximize dispersal (Johnson et al. 2001).

Geoducks are the target of a lucrative international commercial fishery, and recently have become a commercially cultivated species. Assessing potential impacts of hatchery outplants on their wild counterparts will depend, in part, on the characterization of

naturally occurring genetic stock structure. To date there has been no available information on the genetic stock structure of *P. abrupta*, or any of its congeners, and with the high fecundity and longevity of *P. abrupta* potentially maximizing dispersal and genetic homogeneity, large-scale panmixia has been the assumption. Here, we evaluate the null hypothesis of genetic homogeneity in the Strait of Juan de Fuca—Georgia Strait—Puget Sound complex. We examine population differentiation among collections from sites in the complex using 11 allozyme and seven microsatellite loci. As alternative hypotheses, we also consider genetic differentiation due to isolation by distance, as well as stochastic genetic differentiation relative to geographic distance.

A secondary objective is to compare the outcome of parallel analyses using two classes of genetic marker, allozymes and microsatellites. Both are codominant, however allelic variability is usually much higher in microsatellites, providing potentially higher power to detect differences (Goudet et al. 1996, Grant et al. 2000; but see Allendorf & Seeb 2000 and DeWoody & Avise 2000). Because discordant results have been achieved with the two marker classes in a number of studies of genetic variation (e.g., Lemaire et al. 2000, de Innocentiis et al. 2001 but see Allendorf & Seeb 2000), we investigate the relative strengths of these two marker classes for detection of genetic differentiation in a broadcast spawning marine bivalve.

METHODS

Sample Collection

Using SCUBA, divers collected geoducks ($n = 1645$) from a total of 17 sites distributed among the five sub-basins of Puget Sound, the Strait of Juan de Fuca, Georgia Strait, and near Ketchikan, Alaska (Fig. 1). Where possible, sites were chosen based on maximum watercourse distances, least amount of surface water outflow, maximum potential wind-mediated retention, and geographic coverage. Tissue samples were dissected from live animals within 24 hours of harvest. Animals that were not dissected immediately after harvest were held live in flow-through troughs

TABLE 1.

Pairwise watercourse distances (upper triangle) and F_{st} values (allozyme/microsatellite) for 17 collections of *Panopea abrupta* from Puget Sound, Washington and S.E. Alaska. Bold type indicates significant pairwise tests of genotypic (7 microsatellite loci) and genic (11 allozyme loci) differentiation; underlining indicates significant pairwise tests of genotypic differentiation for all 18 loci combined. Indicated significance is at the table-wide Bonferroni P -value of 0.00028 (0.05/178).

supplied with natural seawater. From each specimen, samples were taken for allozyme, microsatellite, or both analyses: approximately 1 cm³ samples of siphon and ctenidia tissues were collected and cryogenically preserved at -80 °C, and foot tissues were divided into 0.5 cm pieces, and stored in 95% ethanol at room temperature (DNA) until laboratory analyses. Sampling the SE Alaska specimens for allozyme analyses was not possible because tissues for microsatellite analyses were obtained opportunistically via a commercial harvest.

Microsatellite Data Collection

Microsatellite genotypes were collected from specimens from sites 1, 2, 6, 8, 11, 12, 13, 15, 16, and 17 (Fig. 1). DNA was extracted from 10 mg of foot tissue using DNEasy 96 Tissue Kits (Qiagen) following the manufacturer's protocol, and used to amplify seven loci. Four of these loci, Pab3, Pab4, Pab5, and Pab6 (Genbank accession numbers AF213657–AF213660) were described by Vadopalas and Bentzen (2000). For Pab5, the primer TAATTCAGGTGGCCGATTT was used as an alternate forward primer. Pab7 (CA repeat, 137–199 bp, primers TTTTCAACTG-GATTGCGTGA and GAACCAATCAATAGAAGCTCCA), Pab8 (compound tetranucleotide repeat, 200–634 bp, primers TCAATGAGATAAAAATGTCGCTAAC and AACAATACCTGCACCAATCT), and Pab9 (GATA repeat, 202–300 bp, primers CGTAAATGTTTATGCCTGCAA and GATCACAAC-TCTCTTTTCTTC) reported here for the first time, were isolated as described in Vadopalas and Bentzen (2000) (Genbank accession numbers AF541256–AF541258). One of each primer pair was labeled on the 5' end with NED (Pab4, Pab8), FAM (Pab5, Pab6, Pab7), or HEX (Pab1, Pab9) fluorescent dyes to enable detection on the MegaBACE 1000 genotyping platform. Reactions were carried out in 384 well microtitre plates in 10 µL volumes containing 10 mM Tris-HCl (pH 8.3), 50 mM KCl, 1.5 mM MgCl₂, 0.01 µM BSA, 0.1% Triton-X100, 0.2 mM each dNTP, 0.5 µM each primer, 0.5 U *Taq* DNA polymerase, and 25–100 ng genomic DNA. Cycling conditions were as follows: 95 °C (3 min); five cycles 95 °C (30 s), 52 °C (30 s) and 72 °C (30 s); 25 cycles 90 °C (15 s), 52 °C (15 s), 72 °C (30 s); 72 °C (40 min) final extension.

Loci were amplified individually and then pooled in sets of four according to nonoverlapping allelic ranges and differing fluorescent end labels. The two electrophoresis multiplexes consisted of Pab3-Pab5-Pab8 and Pab4-Pab6-Pab7-Pab9, and were desalted using hydrated Sephadex G-75 (medium) in Millipore Multiscreen HV 0.45 µm filter plates. Some PCR products were treated with Precipitate (CPG, Inc. New Jersey) following the manufacturer's protocol prior to the desalting step to prolong MegaBACE capillary life. Prepared samples were further diluted 2–5 times, and 2.05 µL added to 2.75 µL MegaBACE loading buffer (Amersham), plus 0.2 µL 900 bp internal size standard (25 bp rungs, Amersham). Pooled samples were denatured in a 96-well heat block at 95 °C for 55 sec and snap-cooled in a 96-well cold block for 1.5 min before electrophoresis through a 96 well MegaBACE 1000 capillary system. Allele sizes were estimated by visual inspection of raw electrophoretic traces using Genotyper 1.0 software (Amersham) and subsequently binned by grouping to the nearest full repeat.

Allozyme Data Collection

Preliminary allozyme screening included over 30 enzymes and a wide array of tissue-buffer combinations. Based on those results, an 11-enzyme, 2-tissue (siphon muscle and ctenidium) screening protocol was developed and used for all subsequent assays. The following enzyme/buffer combinations were used: alanine aminotransferase (ALAT), arginine kinase (ARGK), cytosol nonspecific dipeptidase (PEPA), mannose-6-phosphate isomerase (MPI), and superoxide dismutase (SOD) on TRIS-GLY pH 8.5 (Holmes & Masters 1970); aspartate aminotransferase (AAT-1), glucose-6-phosphate isomerase (GPI), glyceraldehyde-3-phosphate dehydrogenase (GAPDH), and phosphogluconate dehydrogenase (PGDH) on CAME pH 6.8 (Clayton & Tretiak 1972); isocitrate dehydrogenase (IDHP), malate dehydrogenase 9 (MDH), and the *SOD** 155 allele on CAME pH 5.9. The histochemical staining recipes of Harris and Hopkinson (1976) were used to visualize all allozymes except SOD, which was stained according to Fevolden (1989).

For each locus, variant alleles are described in terms of the mobility of the encoded allozymes, relative to the mobility of the

TABLE 2.

Allelic variability in 15 populations of *Panopea abrupta* at 11 allozyme loci. Shown for each population and locus: number of alleles (#), expected heterozygosity (H_e), observed heterozygosity (H_o), p -value for test of conformance to HWE (p), within-population variability (F_{is}), and number of individuals genotyped (n). Means are given in the last column.

most frequently encountered allele during the preliminary survey. Allozyme genotypes were collected from the same sites noted earlier, except for sites 2 and 17. Additional collections analyzed for allozyme variation only included three samples from the Southern Basin, (sites 3, 4, and 5), two samples from the Main Basin (7 and 9), and one sample from Admiralty Inlet (10).

Data Analyses

Genepop version 3.3 population genetics software of Raymond and Rousset (1995) was used to test for conformation to Hardy-Weinberg Equilibrium (HWE) at each locus in each collection using the Markov chain exact test method (Guo & Thompson 1992) for loci with five or more alleles, and the Louis and Dempster (1987) enumeration method for loci with less than five alleles (allozyme loci *PEPA**, *GAPDH**, and *MDH**). Genepop was also used to estimate gametic linkage disequilibrium between loci via the algorithm described by Cockerham and Weir (1979). For

analyses of population differentiation, the genotypic log-likelihood (g) based exact test (Goudet et al. 1996), as implemented in Genepop, was used for all loci. To increase power in groups of loci in which assumptions of HWE were not violated, the genic test (Raymond & Rousset 1995) was used as implemented in Genepop. Weir and Cockerham's (1984) unbiased estimators of single and multilocus F-statistics were computed using the program FSTAT version 2.9.3.2 (Goudet 1995), and F_{ST} values were jackknifed over loci, and bootstrapped over individuals to obtain 95% confidence limits. The programs described in Beaumont and Nichols (1996) were used to evaluate whether F_{ST} values might indicate spatial selection at individual loci. Subsets of the allozyme and microsatellite datasets were used to perform a hierarchical analyses of molecular variance (AMOVA, Excoffier et al. 1992) based on the infinite allele model, to partition the genetic variance into among basins, among collections within basins, and within collections. The significance of the fixation indices among and

TABLE 3.

Allelic variability in 10 populations of *Panopea abrupta* at 7 microsatellite loci. Shown for each population and locus: number of alleles (#), expected heterozygosity (H_e), observed heterozygosity (H_o), p-value for test of conformance to HWE (p), within-population variability (F_{is}), and number of individuals genotyped (n). Means are given in the last column.

within basins and among samples was tested by nonparametric genotypic permutation tests as implemented in Arlequin (Schneider et al. 2000). Two distance matrices, one using linear watercourse distances (Table 1), the other with distances weighted by average subbasin retention time (Ebbesmeyer et al. 1988) between each pair of samples, were tested for correlation with genetic distance matrices via Mantel tests (Mantel 1967) using rank correlations (Raymond & Rousset 1995). A significance level of 0.05 was used throughout, and to avoid Type I error the Bonferroni correction (Rice 1989) was applied for table-wide comparisons.

RESULTS

Within-Population Genetic Diversity

As expected, levels of genetic diversity exhibited by the microsatellites were greater than those observed at allozyme loci (Tables 2 and 3). All of the microsatellites, but only 11 of 30 allozyme loci assayed were polymorphic. The mean number of alleles per allozyme locus per sample was 3.3 to 4.5 (overall mean 4.1), compared with 27.3 to 31.0 (overall mean 29.9) for the microsatellite loci. Expected heterozygosities were 0.01 to 0.76 (mean 0.39) for allozyme loci and 0.88 to 0.99 (mean 0.94) for microsatellites. No significant linkage disequilibrium was detected between pairs of allozyme or microsatellite loci, or between allozyme and microsatellite locus pairs. There were no significant differences among collections in mean observed heterozygosities for either marker set. Over microsatellite loci, the site 1 collection had the greatest mean number of alleles, but this was not significant (ANOVA, $P = 0.98$) due to the high variance over loci.

The allozyme and microsatellite loci differed markedly in respect to their relative conformity to Hardy Weinberg Equilibrium (HWE). Deviations from HWE expectations were generally small for allozymes, with only a single locus out of HWE over all populations after Bonferroni correction ($\alpha = 0.05/11 = 0.0045$). Two allozyme loci were out of HWE in individual collections after Bonferroni correction: *MPI** in the site 3 collection due to heterozygote deficiency and *MDH** in the site 10 collection due to heterozygote deficiency and the site 4 collection due to heterozygote excess. There were 2 additional marginally significant ($P < 0.05$) F_{IS} values involving heterozygote excesses: *ARGK** in the site 13 collection and *GPI** in the site 5 collection. Departures from HWE over all allozyme loci were not significant in any collection after Bonferroni correction ($\alpha = 0.05/15 = 0.0033$, Table 2).

In contrast, the microsatellite loci, with few exceptions, exhibited significantly fewer heterozygotes than expected (in most cases, $P < 0.001$; $\alpha = 0.05/10 = 0.005$, Table 3). The most notable exception was Pab6, which exhibited no significant departures from HWE in any population ($P = 0.0780$, Table 3); however, departures from HWE were also not significant after Bonferroni correction for Pab9 in collections from sites 1, 8, 11, 15, 16, and 17, and, for Pab7 in the site 15 collection and Pab8 in the site 8 collection.

Among-Population Genetic Diversity

Estimated values of F_{ST} were small for both marker classes ($F_{ST} \leq 0.01$, Table 1). Across all samples assayed, the global F_{ST} values for allozymes and microsatellites was small yet significant after bootstrapping ($F_{ST} = 0.002$, $P < 0.001$; $F_{ST} = 0.001$, $P = 0.004$, respectively). Across the eight samples assayed with both marker types, the global F_{ST} value was 0.002, also significant after bootstrapping ($P < 0.001$). The allozyme locus *GPI** and the mi-

cro-satellite locus Pab4 had the greatest influence on F_{ST} , with values of 0.0018 and 0.0005, respectively, after jackknifing (Table 4). Significant genetic differentiation was detected among collections using allozymes ($P = 0.006$), microsatellites ($P < 0.0001$), and both marker classes ($P < 0.0001$) via global genic (allozyme) and genotypic (microsatellites and combined) tests (as implemented in Genepop). There was no evidence for selection at any locus: F_{ST} values for all loci plotted against heterozygosity were within the range of the expected distribution for neutral markers as determined by the Beaumont and Nichols (1996) method.

The hierarchical AMOVAs performed for both allozyme and microsatellite datasets yielded similar results, with 99.71% (allozymes) and 99.75% (microsatellites) of the variation occurring within collections. Variation among basins was nonsignificant for both marker classes (Table 5). Variation among collections was significant for allozymes ($P = < 0.0001$) but not for microsatellites ($P = 0.19062$), and F_{ST} values were significant for both allozymes ($P = < 0.0001$) and microsatellites ($P = 0.041$).

Among the eight populations analyzed with both allozymes and microsatellites, the site 15 collection (Freshwater Bay) was the most genetically divergent; it differed significantly from all common collections except sites 1 (Case Inlet) and 13 (Langley) in pairwise exact genotypic tests with at least one of the two classes of marker (Table 1). Only one of the significant differences, involving site 12 (South Hood Canal) was detected with both allozymes and microsatellites. Significant divergence in genotypic frequencies were observed in four comparisons using both marker sets, but not detected with either marker set separately after Bonferroni corrections. Three of these comparisons involved site 8 (Dyes Inlet), which differed from sites 11, 12, and 16. The fourth comparison revealed differences between sites 11 and 13, again only with both sets of markers combined.

Three other significant differences among common collections (sites 6, 8, and 11) were detected with microsatellites alone. Significant differences between site 15 and sites 3, 4, and 14 for allozymes, and site 2 for microsatellites were also observed. Among populations analyzed only with microsatellites, site 2 stood out as relatively distinct; it differed significantly from sites 8, 12, 13, 15, and 17.

For collections analyzed with both allozymes and microsatellites, pairwise F_{ST} values calculated with allozyme and microsatellite loci separately were correlated (Mantel test, $R^2 = 0.47$, $P = 0.032$), but were typically higher for allozymes (Fig. 2) Without the allozyme locus *GPI**, however, the mean $F_{ST} = 0.0017$, and the T test was no longer significant. There was no correlation between expected heterozygosity and F_{ST} at individual loci for either allozymes or microsatellites. Mantel tests revealed no significant correlations between F_{ST} and either linear or adjusted linear watercourse distance (distance matrix A and B, $P > 0.10$, 0.57 respectively; Fig. 2), not even including the site 17 (Alaska) outgroup (Fig. 3).

DISCUSSION

The results presented are among the first studies of marine bivalve population genetics involving both microsatellite and allozyme loci on the same sample set. In general, geoduck aggregation localities appear genetically homogenous within the region studied, although both marker classes were concordant in the detection of genetic differentiation of the Freshwater Bay (site 15) collection from others. The possible biologic significance of these findings is discussed later.

Within-population Genetic Diversity

In marked contrast to the allozyme loci, most of the microsatellite loci were out of HWE. For allozyme loci, deficiencies of heterozygotes relative to the expectations of HWE have been frequently reported for invertebrates, and bivalves in particular (Zouros & Foltz 1984, Raymond et al. 1997). These deficiencies

have variously been characterized as resulting from null alleles (Foltz 1986), a Wahlund effect (David et al. 1997), inbreeding and genotype-dependent spawning (Rios et al. 1996) or selection (Ridgway 2001). Because the assumption of discrete generations, inherent to the Hardy-Weinberg principle, was violated by this study, that the allozyme loci overall were in HWE may indicate a degree of genetic stability across generations. Because little evi-

Figure 2. *Panopea abrupta* sample site pairwise genetic and geographic distances: Genetic distance, indicated as F_{ST} , over all allozyme (\square) and microsatellite (Δ) loci for each population pair, as a function of watercourse distance (km) between sites. Indicated trendlines for allozyme (solid line) and microsatellite (dashed line) loci are nonsignificant.

dence of overall heterozygote deficiency is apparent in the allozyme data, our data suggest that population level processes are unlikely to be the cause of the heterozygote deficiencies that we observed with microsatellites.

Aside from population level processes, potential causes of the observed heterozygote deficiencies in microsatellites are size homoplasy or mis-scoring of alleles, upper allele dropout, and non-amplifying alleles. Mis-scoring or inadvertent binning of neighboring alleles is akin to size homoplasy, and undoubtedly occurred to some extent in this dataset. Indeed, at a single locus, as many as

seven different microsatellite alleles with identical mobilities were detected via sequencing in the gastropod *Bulinus truncatus* (Viard et al. 1998). Given the high variability of the microsatellite loci used in this study, and the high resolution of the genotyping platform, alleles with very close mobilities are unlikely to have occurred (or to have been inadvertently binned) with a high enough frequency to produce the strong heterozygote deficiencies observed. Upper allele dropout was minimized by both the optimization of PCR conditions and the exploitation of the high sensitivity of the genotyping platform (see Materials and Methods); two alleles could differ in fluorescence intensity by more than 50,000 relative fluorescence units (RFUs), and still be accurately scored via internal lane standards. Even though observed heterozygosities were slightly lower on the less sensitive ABI 373 slab gel platform whose software allowed only a lower fluorescence intensity differential between alleles (Vadopalas, unpublished data), upper allele dropout is unlikely to account for the full magnitude of the deficit of heterozygotes. We explored the possibility of mispriming as a cause of our heterozygote deficiencies during the development of the loci (Vadopalas & Bentzen 2000) by designing primers for alternate flanking sequence. Although the number of alleles present in some individuals changed either from homozygote to heterozygote or vice versa, there was no net change in observed heterozygosities (unpublished data). We were unable to find suitably conserved flanking sequence to alleviate the occurrence of putative mispriming. Thus a likely explanation for the observed heterozygote deficit in our microsatellite data is primer site sequence variation resulting in null alleles. Hedgecock et al. (2004) gave a conservative estimate of one single nucleotide polymorphism (SNP) every 82 base pairs in the Pacific oyster *Crassostrea gigas*; this figure may be considerably higher in geoduck clams. We used the Brookfield (1996) method to calculate the expected

Figure 3. *Panopea abrupta* sample site pairwise genetic and geographic distances: Genetic distance, indicated as F_{ST} , over all microsatellite loci for each population pair including the SE Alaska group, as a function of watercourse distance (km) between sites. Trendline is nonsignificant.

frequency of null alleles in microsatellite loci; for all heterozygote deficient loci the expected null frequency exceeded that of the most common visible allele (Vadopalas, unpublished data). The genotypic bias recognized here is presumed to affect all populations evenly.

The mean expected heterozygosities for microsatellites (0.94) and allozymes (0.390) (Tables 2 and 3) were similar to those found in other marine bivalves. For example, the overall mean expected heterozygosity was 0.261 for 24 allozyme loci in the razor clam *Siliqua patula* (LeClair & Phelps 1994), 0.158 to 0.261 (mean 0.214) for seven allozyme loci in the greenshell mussel *Perna canaliculus* (Apte & Gardner 2001), and 0.114 to 0.696 (mean 0.413) for nine allozyme loci in the bivalve *Spisula ovalis* (David et al. 1997). For microsatellites, Huvet et al. (2000) reported a range of 0.83 to 0.96 (mean 0.88) at four loci in the Pacific oyster *Crassostrea gigas*.

Among-population Genetic Diversity

We detected similar patterns of genetic differentiation with microsatellites and allozymes. Significant differences between site 15 and all other common collections except for sites 1 and 13 were revealed by multilocus genotypic and allelic analyses using the two marker classes separately and combined (Table 1). Genetic differences between site 15 and collections within the Southern Basin were similar: no differentiation was detected between site 15 and site 1 with either marker class, whereas differences were detected between site 15 and the proximate collections from sites 3/4 and 2 with allozymes and microsatellites, respectively. The general concordance between the two marker classes in this study corroborates the findings of others (Scribner et al. 1998, Ross et al. 1999, Allendorf & Seeb 2000, De Woody & Avise 2000) and supports the notion of selective neutrality of allozymes.

Four significant pairwise exact test comparisons with all markers combined were not significant for either marker class alone. Greater power to detect differentiation may be gained by an increase in the number of markers used, rather than the number of alleles per locus or individuals per collection (Ferguson & Danzmann 1998). Although based on relatively low P values, the differentiation in three of four significant comparisons appears derived from microsatellite rather than allozyme genotype frequency variation (Table 1).

There were some discordant results between the marker classes. Differences between site 15 and sites 6, 8, and 11, detected with microsatellites, were undetected with the allozyme loci in pairwise exact tests, although the pairwise site 15-11 and 15-8 allozyme comparisons were marginally significant ($P = 0.06$ and 0.04 , respectively). Whether this possible discordance is indicative of greater statistical power attributed to markers with greater variability (Goudet et al. 1996) is unclear.

We plotted the relationship between expected heterozygosity and F_{ST} per locus over all populations, and found no significant correlation. However, pairwise F_{ST} values were generally lower for microsatellites than for allozymes (Fig. 2, Table 1), although this difference was only significant with the inclusion of the allozyme locus GPI. Jin and Chakraborty (1995) demonstrated theoretically that high mutation rates and stepwise mutation can reduce F_{ST} , a feature of microsatellites also simulated by Balloux et al. (2000). Charlesworth (1998) and Hedrick (1999) showed that compared with less variable markers, higher marker variability reduced F_{ST} values. Nevertheless, highly variable markers are powerful in

exact tests of differentiation not just by virtue of their sensitivity to gene flow (Ross et al. 1999) but also because their high variability imparts greater statistical power (Estoup et al. 1998). The paradox of lower F_{ST} parameter estimates but greater power to detect differentiation in exact tests among highly variable loci was discussed by Hauser and Ward (1998), who concluded that F_{ST} values from microsatellites can be poor estimators of genetic differentiation, and call for the use of multiple marker classes in studies of genetic structure such as used in the present study.

Biological Significance

Whether the statistically significant genetic differences among populations detected with both sets of markers together and independently are biologically significant is difficult to assess, because the pattern is inconsistent. With both allozymes and microsatellites, the differentiated pairs include site 15 and 5 other sites: 4 within Puget Sound, and the single Georgia Strait sample (16). The significant genetic differences between sites 15 and 12 and Southern Basin collections correlate with watercourse distance, whereas the differences between the outer Straits collections do not. In addition, the differences detected with microsatellites between the site 2 collection in the Southern Basin and collections in nonadjacent basins/inlets, including S.E. Alaska seem to correspond to IBD, yet with these same markers we were unable to detect differentiation between the S.E. Alaska collection and any other population surveyed. Greater differences were detected on a scale of 100 km than 1000 km; the lack of correlations between F_{ST} and distance for either class of marker (Figs. 2, 3) and the lack of differentiation between site 17 (S.E. Alaska) and all other collections in the complex except site 2 reinforce our conclusion that a simple IBD model does not apply to the current dataset.

Aside from general panmixia, there are a number of alternate explanations for our failure to find IBD. First, it may be that neither the weighted nor the unweighted distance matrix sufficiently approximates abiotic factors affecting larval dispersal, and that we missed an isolation by distance signal through an inappropriate circulation model. The complexity of Puget Sound's hydrology, bathymetry, currents, and wind-driven surface waters notwithstanding, there is a general seaward surface water flow from south to north in Puget Sound, with vertical mixing at the sills where approximately 50% of the surface outflow is cycled back to the basin of origin (Ebbesmeyer et al. 1984, Geyer & Cannon 1982). Particles released in one basin will generally be exchanged throughout the Puget Sound complex before exiting the system through the Strait of Juan de Fuca (Ebbesmeyer et al. 1988). However, water mass retention times in Hood Canal and Whidbey basins can be as high as 9 months (Cox et al. 1984) and easily exceed the 4 to 6 week geoduck pelagic stage. Thus both distance matrices oversimplify the complexities of estuarine circulation and passive larval dispersal in the Puget Sound complex.

Second, the behaviors of geoduck larvae in relation to currents, temperature, photoperiod, and phototropism are not well understood. Larval phototaxis may have a large impact on associations with a particular water mass. Because we have attempted to integrate some gross circulation rates, larval behaviors and differential rates of recycling at sills may play important roles in the degree of larval transport (Ebbesmeyer et al. 1998) and gene flow among basins that we have not sufficiently modeled.

Third, the low differentiation exhibited between the SE Alaska collection and those in Washington may be due not to high gene

flow, but instead to the tendency of highly variable microsatellites to underestimate population structure in cases of low gene flow, as demonstrated both empirically and via simulations by (Balloux et al. 2000). A combination of array size constraints (Nauta & Weissing 1996, Calabrese et al. 2001), size homoplasy/binning (Viard et al. 1998, Angers et al. 2000), and statistical noise associated with the allele:specimen ratio, perhaps strongly associated with our highly variable microsatellite loci, may confirm observations that microsatellites can underestimate genetic differentiation (Hauser & Ward 1998), especially in cases where the separation is recent.

The genetic differences found may be due to some hydrographic factors affecting geoduck genetic population structure. Differences in geoduck settlement have been hypothesized to be due to localized hydrodynamics (Zhang & Campbell 2004). The differentiation of the site 15 collection may be due to difficult emigration caused by strong oceanographic conditions that occur in the Strait of Juan de Fuca. A sill, roughly between Victoria, BC and Dungeness Spit, Washington, separates the inner and outer Strait (Fig. 1). Intense homogenization of surface and deep waters occurs at the sill, where summer water temperatures are colder than they are elsewhere in the region, perhaps serving as a barrier to successful larval immigration. A possible isolating mechanism in this general locality is suggested by the allele frequency divergence in Butter clams (*Saxidomus giganteus*) found by Johnson and Utter (1973).

The relatively few differentiated collections may reflect selection, because the differences may be primarily driven by a minority of loci linked to genes under selection. Among the allozyme loci, the significant differentiation of site 15 from other collections was driven primarily by the allozyme locus *GPI**. *GPI* seems to be under temperature selection in *Mytilus edulis* (Hall 1985) with a latitudinal gradient among alleles (Koehn et al. 1976, Koehn et al. 1984). Both temperature and salinity vary less at site 15 compared with other more estuarine localities; a similar mild selective effect might explain the observed differences in *GPI** allele frequencies in geoducks. Without *GPI**, jackknifing over collections resulted in a global F_{ST} of 0.00175 (Table 4), indicating *GPI** has the strongest effect among allozymes loci on global F_{ST} . Without site 15, jackknifing over loci resulted in an overall F_{ST} for *GPI** of 0.00088, further indication that the differentiation may be due to this locus. However, no evidence that this locus is under selection was detected using the method of Beaumont and Nichols (1996).

Another possible cause of the seemingly random genetic differentiation could be the scale on which we are sampling. Seemingly random differentiation can exist on a very fine scale due to variable settlement patterns (Larson & Julian 1999). *Panopea abrupta* larval cohorts may aggregate in clusters to increase dispersal. If larvae in the natural environment increase their drag coefficient by rafting together using a combination of byssus and mucus as we have observed in the hatchery environment (Vadopalas, unpublished data), they may remain associated until settlement. Some separation of larvae would still occur via turbulence, postsettlement byssus drifting (Sigurdsson et al. 1976), or pedal locomotion over the substrate (Cole & Beattie 1991). Nevertheless, some degree of clustered dispersal may explain our results. If it does occur, some degree of increased relatedness within, and increased differentiation among, collections on a subkilometer sampling scale may be detectable. Studies are underway to investigate microspatial genetic variation in *P. abrupta*.

We assume the geoduck collections in this study consisted of overlapping generations, because ages range from 12 to 131 for a

random sample of *P. abrupta* from Puget Sound (Goodwin & Shaul 1984). With the high longevity, early reproduction, and no apparent reproductive senility (Sloan & Robinson 1984), the mean generation time for geoduck clams is approximately 30 years; a random sample of 100 geoducks is likely to include more than 50 year classes and many overlapping generations. Because overlapping generations violate assumptions of many population genetic models (Hartl & Clark 1997), the overall effect of our random sampling of cohorts within each collection should be to minimize the effect of temporal genetic drift (Jorde & Ryman 1995). However, *P. abrupta* may use the strategy modeled by Ripley (1998) in which bivalves with high longevity and fecundity can wait many years until the relatively rare occurrence when conditions are conducive to mass reproductive success. This strategy would maintain genetic variability over long temporal scales, but may create stochastic differences on shorter temporal scales. Indeed, in another large collection for which we have age data (genotype and age data to be reported in a forthcoming study), 27% of the specimens are of a single year class. If separate year classes are genetically differentiated via sweepstakes recruitment (Hedgecock 1994) in years, intervening between episodes of strong recruitment genetic variability would be reduced within cohorts. Supporting the sweepstakes hypothesis, David et al. (1997) demonstrated significant differences between cohorts in the clam *Spisula ovalis*. Li and Hedgecock (1998) demonstrated significant genetic heterogeneity among larval *Crassostrea gigas* cohorts, and Moberg and Burton (2000) detected greater heterogeneity among recruits than among adults over similar spatial scales.

Our results are similar to those of Johnson and Black (1984) and Edmands et al. (1996) who found what appeared to be stochastic genetic differentiation in marine invertebrates (*Siphonaria jeanae* and *Strongylocentrotus purpuratus*, respectively), with genetic homogeneity on a broad spatial scale and heterogeneity on a fine scale. Similar observations for other marine taxa exist (see Shaklee & Bentzen 1998 for a review). Whether the heterogeneity detected in this study reflects temporally stable differences among local populations of geoduck clams, or are instead due to large variation in year class strength and strong bias in reproductive success among spawners is the subject of ongoing investigations.

CONCLUSION

In general, genetic homogeneity, or panmixia, was found among collections of Puget Sound geoducks, with only a few statistically significant differences that are inconsistent with an isolation by distance model. To maximize the signal of genetic differentiation relative to random noise, temporal replication is highly recommended (Waples 1998). Temporal homogeneity was assumed among our collections, but given age data currently on hand for other geoduck clam collections, such an assumption is unlikely to be accurate. A temporal Wahlund effect is possible if, for example, a large proportion of a single year class comprises the site 15 sample. Thus, it is difficult to conclude whether the genetic differences between this site and others represent long-term effects of reproductive isolation leading to separate evolutionary trajectories, thermal selection, or simply stochastic variation. Including only those collections within the Puget Sound, no significant differences were detected with allozymes, and yet four differences were detected with microsatellites. Again, this differentiation among geoduck collections may be temporally unstable over a scale much longer than a few generations. Whether such patterns

of "chaotic genetic patchiness" apply to other marine taxa in the Puget Sound region remains to be investigated. We emphasize the need to study both the spatial and temporal scales of sweepstakes recruitment, so fishery managers can incorporate genetic population structure into harvest and culture management models.

ACKNOWLEDGMENTS

The authors thank two anonymous reviewers for helpful comments and suggestions that greatly improved the manuscript. The

authors also thank and are indebted to J. Shaklee, P. O'Reilly, F. Utter, C. Friedman, L. Hauser, and J. Davis for helpful discussions; A. Bradbury, R. Sizemore, D. Rothaus, M. Ulrich, and M. Walker for providing geoduck samples; and C. Bowman, R. Colwell, A. Drape, C. Duff, B. Ingram, E. LeClair, A. Marshall, K. Obrien, K. Sweeney, and N. Switzler for help with dissections. This work was supported by Washington Sea Grant #NA76RG0119. B.V. was additionally supported by the Roy Jensen Fellowship, School of Aquatic and Fishery Sciences, University of Washington.

²University of Georgia, Savannah River Ecology Laboratory, Aiken, South Carolina 29802

ABSTRACT The variable coquina clam, *Donax variabilis*, is one of the most common inhabitants of exposed sandy beach intertidal and shallow subtidal zones in the southeastern United States. Its exceptional burrowing and migratory behaviors are well documented, as are its biogeographic distribution and phylogenetic relationships. However, basic life history parameters such as season and rate of shell growth and longevity are poorly constrained for this species, usually estimated from size-frequency analyses of sample populations. High-resolution sampling of individual *D. variabilis* shells, and analysis of the oxygen isotopic variation in these samples, provides an alternate method of assessing shell growth and longevity in this species with a high degree of precision. Comparison of isotopic paleotemperature profiles with local seawater temperatures in the northeastern Florida study region indicates rapid shell growth (>4 mm/month) during a life span of 3 to 5 months, substantially shorter than most previous estimates. Detailed analysis of two modern shells indicates growth during spring and summer whereas four Archaic period archaeological shells revealed a summer-autumn growth record. In all cases the largest archaeological shells were substantially bigger than the largest modern shells, reflecting a greater longevity by about 2 months. Although recruitment can be fairly continuous throughout the year, size-frequency analyses of *D. variabilis* in separate years at the same locality reveal substantial interannual differences in population dynamics.

KEY WORDS: *Donax variabilis*, oxygen isotopes, shell growth, longevity, Florida

INTRODUCTION

The variable coquina clam, *Donax variabilis* Say, 1822, is one of the most common, recognizable bivalve mollusks from sandy beach habitats of the southeastern United States. It is found from Virginia to southern Florida and around the Gulf Coast to Texas (Ruppert & Fox 1988). Like other members of the Family Donacidae, *D. variabilis* is often the dominant macro-invertebrate inhabiting the high-energy environment of exposed sandy beaches where it often occurs in extremely high densities (Ansell 1983, Brown & McLachlan 1990, Pearse et al. 1942, Wilson 1999). In some cases *Donax* clams account for over 95% of the macrofaunal biomass on such beaches (McLachlan et al. 1981).

Donax clams are excellent burrowers, ideally suited to life in the surf zone (McLachlan & Young 1982, Trueman & Ansell 1969). The wedge-shaped outline of their shells facilitates penetration into the substrate. In addition to rapid burrowing, *D. variabilis* is also noted for its mobility, moving up and down the beach with the tides (Turner & Belding 1957), responding in a complex manner to wave action and especially to the acoustic shock of breaking waves (Ellers 1995a, Ellers 1995b). On longer time scales, Ruppert and Fox (1988) report a seasonal cycle of migration across the beach zone, down into the shallow sublittoral in fall, and returning onto the beach as juveniles in the late winter. This rather nomadic lifestyle, combined with its supreme ability as a rapid burrower, has enabled this species to colonize the sands of exposed beaches that otherwise are fairly devoid of macrofauna (Wilson 1999).

Despite its familiarity to scientists and shell collectors alike, the taxonomic status of *D. variabilis* has been debated for decades. Morrison (1971) envisioned 2 largely sympatric species, *D. variabilis* and *Donax parvula* Philippi, 1849, with the former further subdivided into a subspecies occurring in the southwestern portion of the range, *D. variabilis roemeri* Philippi, 1849. By contrast, Abbott (1974) and Dance (1990) considered *D. parvula* an ecomorph of *D. variabilis*. From studies of morphology, genetics and

ecology, Nelson et al. (1993) concluded that *D. variabilis* and *D. parvula* were highly similar, but distinct species.

Using molecular techniques (RAPD DNA markers), Adamkewicz and Harasewych (1996) seem to have resolved the lingering systematics issues as well as simplified our understanding of the biogeography of *Donax* in eastern North America. They found no evidence for the existence of the subspecies *D. variabilis roemeri* and found *D. parvula* to be indistinguishable from the subtidal *Donax fossor* Say, 1822, with the latter synonym having taxonomic priority. Their biogeographic assessment has *D. variabilis* sharing both the Atlantic and Gulf coasts with a smaller, subtidal species, *D. fossor* on the Atlantic coast and *Donax texianus* Philippi, 1847, in the Gulf of Mexico. The Florida peninsula separates the two subtidal species (Adamkewicz & Harasewych 1996).

The principal distinguishing feature between *D. variabilis* and *D. fossor*/*D. parvula* is the angle of the dorsal margins of the shell on either side of the umbo (Wilson 1999). Unfortunately, juvenile specimens often cannot be assigned to one species or the other (e.g., Bonsdorff & Nelson 1992) and ecophenotypic variation can further complicate specific determination, particularly in the field. Hence, we considered all small shells (≤ 3 mm) collected for this study to be *D. variabilis*, combining them with the larger specimens with which they were collected.

Despite its ecological importance, abundance and visibility on exposed sandy beaches, several key life history parameters of *D. variabilis* such as growth rate and longevity are known only to a first approximation with widely divergent estimates in the literature. This is particularly significant when *D. variabilis* is used as a model organism in ecological studies involving population dynamics and energy budgets on sandy beaches (Wilson 1999), or in investigations of the roles of biotic versus abiotic factors in determining spatial distribution and recruitment of beach fauna (Schoeman & Richardson 2002). Longevity estimates for *D. variabilis* range from less than 1 year (e.g., Bonsdorff & Nelson 1992) to higher than 3 years (e.g., Morrison 1971). At least part of the explanation for the lack of accurate data is the traditional method for assessing growth and longevity in this species—analysis of

*Corresponding author. E-mail: dsjones@flmnh.ufl.edu

size-frequency diagrams—an approach with many inherent problems (Mikkelsen 1985). Other techniques such as mark-and-recapture studies are impractical because of the movements and high mortality of these clams (Mikkelsen 1985), and growth rings on the shell are indistinct, not useful for age determination (Wilson 1999). In this study we use oxygen isotopic variation in shell carbonate to produce high-resolution records of seasonal shell growth and longevity in *D. variabilis*.

Florida coquina clams normally are not exploited as a food resource by humans today; however, archaeological sites in northeastern Florida attest to the fact that preColumbian people consumed vast quantities of coquina clams between the middle Archaic (ca. 5700 y BP) and St. Johns (ca. 400 y BP) periods (Milanich 1994). This study of growth and longevity in *D. variabilis* originated from an investigation of archaeological specimens recovered from coastal shell middens in northeastern Florida to determine if there was a seasonality to ancient shellfish harvest (Jones et al. 2003, Quitmyer et al. 2004). In addition to examining archaeological shells, year-round collections of living coquina clams were made to establish a modern analogue for comparative purposes. Oxygen isotopic profiles of both modern and archaeological shells document rapid seasonal growth and shorter life spans than previously acknowledged for this diminutive but important bivalve species.

MATERIALS AND METHODS

The earliest evidence for human use of marine resources in northeastern Florida comes from the many Archaic period coastal archaeological sites recognized from this region (Milanich 1994). Particularly abundant in these shell middens are specimens of *D. variabilis* that often dominate the zoo archaeological component of any particular site. Collections of *D. variabilis* have been made at many of the more prominent excavation sites by archaeologists and students from the University of Florida (Quitmyer et al. 2004). These are housed in the collections of the Environmental Archaeology Program at the Florida Museum of Natural History, University of Florida, Gainesville.

Four archaeological shells of *D. variabilis* were selected for oxygen isotopic analysis from among the largest specimens in the museum collections. Large specimens were chosen to increase the likelihood of measuring maximum longevity. Two well-preserved shells from the Preceramic Archaic were selected, one each from the Crescent Beach (4240 ± 80 corr. ^{14}C yr BP) and Spencer's Midden (5570 ± 80 corr. ^{14}C yr BP) sites (Fig. 1). The shell lengths of these specimens were 23.1 mm and 21.5 mm, respectively. In addition, two well-preserved specimens were selected from the Orange Period Archaic material, one shell (21.3 mm) from the Rollins Site (3760 ± 60 corr. ^{14}C yr BP) and another (20.5 mm) from the Guana Shell Ring (3600 ± 50 corr. ^{14}C yr BP).

To establish a modern analogue for comparison with the archaeological coquina shell material, *D. variabilis* specimens were live-collected at monthly intervals at Matanzas Beach between December 2001 to November 2002. The collection site on Anastasia Island is located just south of the beach access ramp from Fort Matanzas National Monument (N 29.7174° ; W 81.2310°), north of the Matanzas Inlet, in the same vicinity and water depths where indigenous people could have harvested coquina clams thousands of years ago (see Fig. 1). Specimens were collected in the intertidal and shallow subtidal zones (≤ 1.5 -m depth) for a consistent 40-min interval each month. Live clams were water-

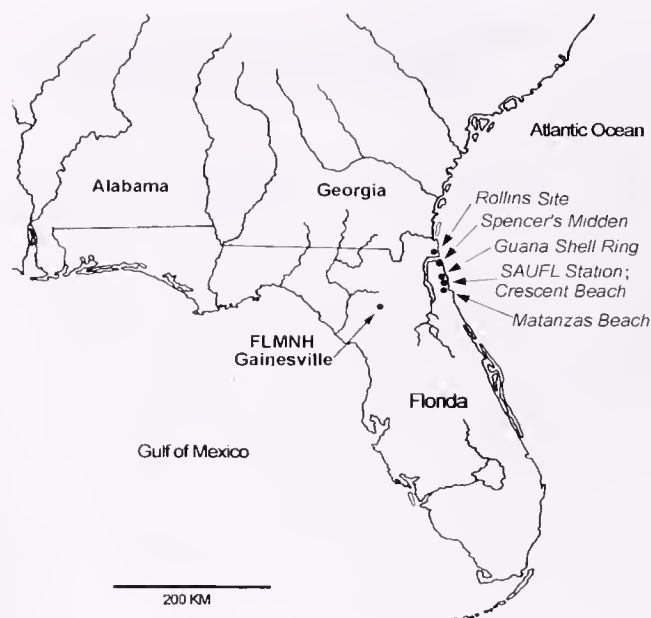

Figure 1. Location map showing archaeological midden sites along the northeastern coast of Florida, including site of modern *D. variabilis* collection at Matanzas Beach and SAUFL station at Crescent Beach.

sieved from bulk samples scooped from the sandy bottom using a 1.59 mm-gauge brass sediment sieve, identical to that used to sieve archaeological materials. The clams were bagged, stored in a cooler, and transported back to the museum where they were quickly frozen and stored. Soft tissues were removed by water maceration at a later date.

A comparable assemblage of *D. variabilis* shells, live-collected at monthly intervals between January to December 1988 at the same locality, was also available at the museum. These shells were collected by Dr. Michael Russo during the course of research in the Department of Anthropology at the University of Florida (Quitmyer et al. 2004).

The maximum shell length, anterior to posterior, was measured for each shell in every monthly collection from both data sets using a dial caliper. The monthly shell length frequencies were calculated and plotted in 1-mm increments to facilitate the temporal comparison of shell size variation in the populations. Similar size-frequency data were constructed by Quitmyer et al. (2004) for archaeological coquina clam shells excavated from middens in northeastern Florida. Two of the largest modern shells were selected for stable isotopic analysis (13.1 mm, 13.2 mm). These specimens were collected by Russo in July 1988.

When carefully sampled in ontogenetic sequence from the umbo to the ventral shell margin (Fig. 2), the pattern of oxygen isotopic variation across a bivalve shell can provide a wealth of information about seasonal growth, shell growth rates, longevity, and season of death (Jones & Quitmyer 1996, Jones et al. 1983, Wefer & Berger 1991). To assess these parameters in *D. variabilis*, and to look at possible changes through time, sequential samples of shell carbonate were recovered from the two modern and four archaeological shells.

Prior to sampling each valve was cleaned following Andrus and Crowe (2002), with a wire brush under distilled water and then treated with a 30% solution of H_2O_2 . After rinsing in distilled water and drying in a vacuum oven, the samples were mounted

Figure 2. Archaeological *D. variabilis* shell from Guana Shell Ring site showing sampling grooves from milling procedure to collect powders for oxygen isotopic analyses. Scale bar divisions = 2 mm.

onto glass slides with epoxy and fixed to the sample stage of a Merchantek EO Micromill at the Savannah River Ecology Laboratory. Carbonate samples were milled from the outer surface of the valve in shallow, 25 μm -deep grooves parallel to the growth lines. Each sampling groove was approximately 100- μm wide. The spacing between adjacent grooves averaged 200 μm with grooves near the ventral margin slightly more closely spaced than those near the umbo, reflecting the slowing of shell growth with age (see Fig. 2).

The isotopic analyses were conducted in the Light Stable Isotope Mass Spectrometry Laboratory, Department of Geological Sciences, University of Florida. The powdered CaCO_3 samples were analyzed according to standard techniques (Jones & Quitmyer 1996) which involved an initial reaction *in vacuo* with 100% orthophosphoric acid at 90°C for 0.25 h. An on-line automated carbonate-preparation system facilitated the production and purification of the evolved CO_2 gas. The isotopic differences between the derived CO_2 gas and the VPDB standard were determined with a VG Isogas PRISM Series I mass spectrometer equipped with triple collectors and micro-inlet system. All values are reported in standard δ notation where:

$$\delta^{18}\text{O} = [({}^{18}\text{O}/{}^{16}\text{O})_{\text{sample}} / ({}^{18}\text{O}/{}^{16}\text{O})_{\text{standard}} - 1] \times 10^3 \text{ per mil (‰)}$$

The weight of the individual microsamples was so low that replicates of unknowns could not be run and often required that adjacent samples be combined. However, replicated standards run before and after sample strings varied by less than $\pm 0.1\text{‰}$.

The $\delta^{18}\text{O}$ value of seawater from the Matanzas Beach collection site was measured via CO_2 equilibration following Socki et al. (1992) at the University of Georgia, Geology Stable Isotope Laboratory. Five monthly samples were analyzed (December to March & August), providing a measure of seasonal $\delta^{18}\text{O}$ range. Precision was estimated based on analysis of the laboratory working standard of Athens tap water to be ± 0.05 (1 σ). The $\delta^{18}\text{O}$ values of seawater at the Matanzas Beach collection site were very consistent (Dec. 1.0‰; Jan. 1.2‰; Feb. 1.0‰; Mar. 1.1‰; Aug. 1.1‰), averaging 1.08‰ SMOW ($\pm 0.08\text{‰}$, 1 σ ; maximum range = 0.2‰).

We calculated the temperature of the water in which the shell carbonate formed using the paleotemperature equation of Gross-

man and Ku (1986) for the temperature-dependent fractionation of aragonite in mollusks relative to seawater:

$$T(^{\circ}\text{C}) = 21.8 - 4.69 [\text{shell } \delta^{18}\text{O}_{\text{VPDB}} - (\text{seawater } \delta^{18}\text{O}_{\text{SMOW}} - 0.2\text{‰})].$$

The paleotemperature data from the coquina shells are presented in ontogenetic sequence and graphed to the mean weekly seawater temperature curve based on historical measurements made in 1988 at the nearby St. Augustine National Data Buoy Center station, SAUFL (<http://www.ndbc.noaa.gov/Maps/Florida.shtml>).

RESULTS

At Matanzas Beach, 2,493 specimens of *D. variabilis* were collected in 1988 by Russo and measured as part of this study. Another 2,545 specimens were measured from the collection made in 2001 to 2002. This latter number represents the total of all specimens collected each month except April 2002 when 28,372 specimens were collected during the usual 40-min regimen. A subset of shells (344 specimens) equal in weight to the previous month's sample (March) was selected from the April 2002 sample for measurement. The monthly length-frequency relationships for each of these samples are illustrated in Figures 3 and 4.

Each of the monthly graphs for 1988 (see Fig. 3) reveals a concentration of specimens at the smaller sizes. During winter (December to February) most of the shells in the population ranged between 2–6 mm, reflecting a preponderance of new recruits entering the population. A small percentage of larger shells were observed, up to 12 mm. In the spring (March to May) clams were more abundant than during any other season. Most shell lengths ranged between 2–10 mm with peaks at 3, 5, and 7 mm, indicative of shell growth and continued recruitment. A few specimens in the May sample reached 14 mm. The summer quarter (June to August) was marked by a very strong peak at 3 mm indicating that recruitment remained vigorous. Shell lengths ranged between 2–13 mm. Although individuals were scarce compared with other seasons, the greatest proportion of large shells was encountered in summer (see Fig. 3). By autumn (September to November) the average shell length of the population had declined with a major influx of juvenile shells in the 2–5 mm range and a decrease in the percentage of large shells.

The monthly graphs for 2001 to 2002 (see Fig. 4) show similarities and significant differences from those of 1988. The winter months were characterized by specimens in the range of 1–11 mm. Peaks at 2, 4, and 5 mm in successive months reflect an influx of new recruits in December followed by individual shell growth and a concomitant increase in the average shell length throughout the winter. The continuation of this pattern during spring resulted in peaks at 3, 7, and 10 mm. Except for June 2002, the sample sizes in July and August were very small, insufficient for a robust interpretation of patterns. The autumn samples show a very strong peak at 3 mm and also some of the largest shells recovered in either year of collecting, up to 15 mm. Heavy recruitment is indicated as well as individual shell growth by older specimens.

High-resolution milling of the *D. variabilis* shells resulted in powdered CaCO_3 samples whose weights were toward the lower limits of those typically analyzed. Therefore, successive samples were combined to insure a sufficient sample size. With respect to the modern shells, this resulted in 8 unique samples for specimen

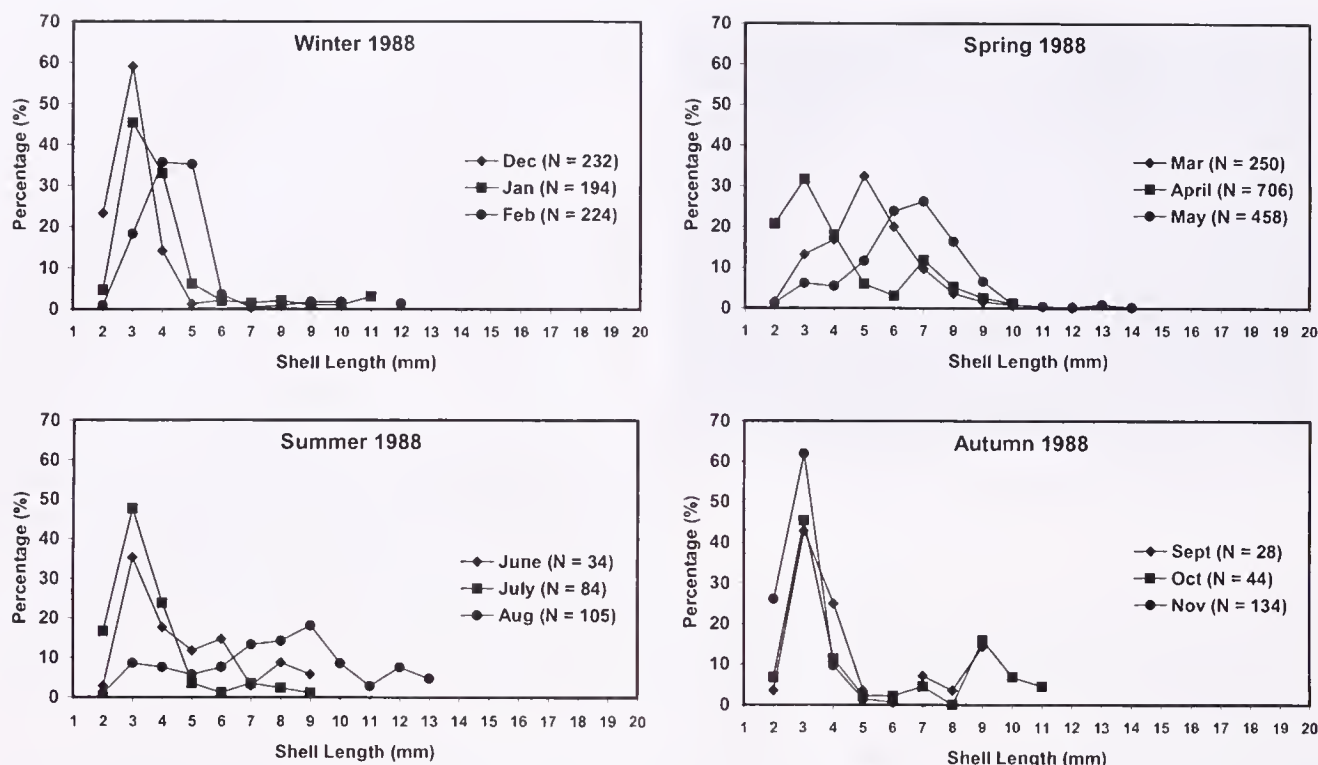

Figure 3. Shell length-frequency diagrams for *D. variabilis* collected at monthly intervals during 1988 from Matanzas Beach, FL.

#1 (13.1 mm) and 13 unique samples for specimen #2 (13.2 mm). Oxygen isotopic analyses of these samples produced values that ranged from 1.91‰ to 0.03‰ for specimen #1 and from 1.61‰ to 0.83‰ for specimen #2.

Figure 5 shows the mean weekly sea surface temperature variation at Matanzas Beach for 1988 based on historical measurements made at the nearby St. Augustine National Data Center Buoy station, SAUFL. The oxygen isotopic data from two shells col-

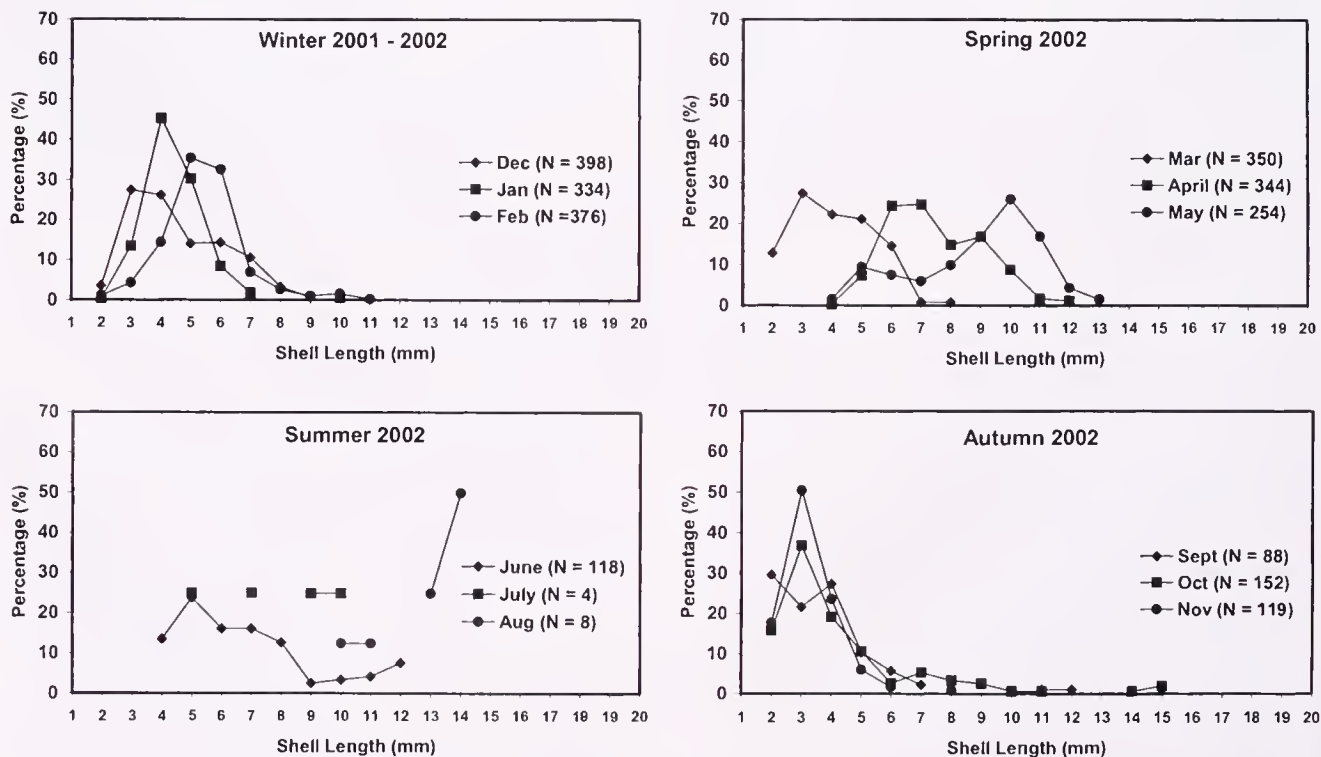

Figure 4. Shell length-frequency diagrams for *D. variabilis* collected at monthly intervals from December 2001 to November 2002 at Matanzas Beach, FL.

Figure 5. Weekly mean sea surface temperature data (black circles) from the SAUFL station for 1988 with isotopic paleotemperature profiles from two modern specimens of *D. variabilis* plotted in open symbols. Longevity of specimens corresponds to the length of the isotopic records, approximately 13 wk (14–26).

lected in July 1988 were converted to paleotemperatures and overlain in ontogenetic sequence onto the portion of the temperature curve that provided the best fit.

With the exception of only one data point, the isotopic paleotemperature data exhibit an excellent fit to the segment of the curve corresponding to spring and early summer. The exceptionally close match confirms the absence of vital effects influencing shell $\delta^{18}\text{O}$ values in *D. variabilis*, as in most mollusks (Wefer & Berger 1991). The shell-edge paleotemperature values correspond nicely with the water temperature at the time of collection in early July 1988. The isotopic records indicate that shell growth in both specimens occurred over a 13-week interval, approximately corresponding to weeks 14 to 26 of the year (mid April to early July).

In a similar manner, the four larger archaeological shells were sampled and analyzed for oxygen isotopic ratios. A total of 18 samples was analyzed from the Crescent Beach specimen. The $\delta^{18}\text{O}$ values ranged from 0.29‰ to 1.55‰. From the Spencer's Midden shell a total of 20 samples was analyzed whose $\delta^{18}\text{O}$ values ranged between 1.16‰ and 1.37‰. A total of 20 samples from the Rollins Site shell yielded $\delta^{18}\text{O}$ values that ranged between 1.26‰ and 1.96‰. From the Guana Shell Ring specimen, 13 samples were analyzed. These produced $\delta^{18}\text{O}$ values that ranged from 0.88‰ to 1.49‰.

The oxygen isotopic data were converted to paleotemperatures and these were overlain onto the seawater temperature curve (Fig. 6). The results are comparable with those achieved for the modern shells with a few important differences. The paleotemperature profiles for the two Preceramic Archaic shells from the Crescent Beach and Spencer's Midden sites show the closest correspondence with weeks 25 to 45 of the annual temperature curve. This pattern suggests shell growth occurred for about 21 weeks, from late June into mid-November. The paleotemperature profiles for the two younger shells from the Orange Period Archaic sites (Rollins and Guana Shell Ring) reveal a similar pattern. Shell growth over a period of about 20 weeks is indicated, corresponding to weeks 24 to 43 of the year, mid-June to late October.

All four archaeological shells were larger in size than any of the modern shells collected as part of this study. The results indicate that the ancient clams achieved their larger size by growing for a longer period of time (i.e., 8–9 wk longer) than their modern counterparts. Whereas maximum longevity among the modern shells was approximately 3 months, the archaeological specimens

Figure 6. Weekly mean sea surface temperature data (black circles) from the SAUFL station for 1988 with isotopic paleotemperature profiles from two Preceramic Archaic shells (upper) and two Orange Period Archaic shells (lower) of *D. variabilis* plotted in open symbols. Longevity estimates for ancient shells correspond to the lengths of the isotopic records, approximately 21 wk (25–45, upper) and 20 wk (24–43, lower).

lived for up to 5 months. The paleotemperature records indicate that each of the four archaeological shells was harvested in autumn. Although the seasonal pattern of paleotemperature change recorded by the oxygen isotopes in the archaeological shells mirrors that of modern seawater at this site, the values reveal a consistent negative offset from modern conditions. The paleotemperature values from both archaeological periods reflect ocean water conditions in this region that were warmer than modern temperatures by about 3.5°C.

DISCUSSION

Despite its abundance and familiarity to scientists and shell collectors, key life history parameters such as growth rate and longevity are poorly constrained for *D. variabilis*. As this short-lived but abundant bivalve finds increasing use in ecological modeling of exposed beach ecosystems, it is essential that basic life history parameters are determined more precisely.

The oxygen isotopic evidence from modern and archaeological shells of *D. variabilis* provides the most accurate assessment of seasonal shell growth and longevity in this species to date. These data serve to refine previous estimates that were based largely on size-frequency analyses that required critical assumptions to be made about the seasonal timing of recruitment and migrations, assumptions that may or may not be warranted. Inherent problems in the interpretation of life-history information from size-

frequency data are acknowledged by several authors including Mikkelsen (1985, p. 310) who states, "... repeated sampling of the population to construct length-frequency graphs was used, although problems exist with its use."

In his overview of the biology of the genus *Donax*, Ansell (1983) reported that most species are short-lived with life spans of 1–2 y, rapid growth to maximum size, and early maturity. Morrison (1971) suggested that *D. variabilis* has a 2-year life span, and that in some cases individuals may survive a third year. Ansell (1983) reported a 1- to 2-year life cycle for *D. variabilis*. Mikkelsen (1985) estimated that *D. variabilis* in Florida grew at a rate of 3.0–3.7 mm/month in the summer months and that, "the majority of individuals probably live for approximately 1 year, with a few entering a second year" (Mikkelsen 1985, p. 310). This conclusion generally agrees with Loesch (1957) and Pearse et al. (1942) who also used length-frequency graphs to examine growth and longevity in this species.

"Bonsdorff and Nelson (1992) estimated a maximum growth rate of 3.43 mm/month for a Florida population of *D. variabilis*, at which rate the animals would grow to maturity in just 2 months" (Wilson 1999, p. 78). The oxygen isotope results achieved in this study support such rapid growth rate estimates and reduced longevity (i.e., months, not years). In fact, the growth rates calculated from our isotopic data are even higher, 4.3–4.4 mm/month for the modern specimens and 4.1–4.6 mm/month for the archaeological shells.

The isotopic data also call into question whether any of these clams actually survive for 1 full year as the modern and archaeological shell isotope records indicated life spans of 3 to 5 months, respectively. Admittedly both the modern and archaeological specimens were live-collected by humans and therefore it could be argued that they still had the potential to grow larger and live longer. However, both sets of shells were among the largest specimens out of the thousands recovered in either the modern or zooarchaeological collections, thereby minimizing this possibility. Our results cast serious doubt on previous longevity estimates for this species that hypothesize growth and survival into a second or even a third year of life.

In a study involving *D. variabilis* from the South Carolina coast, Wilson (1999, p. 69) states: "Survival of *Donax* beyond a shell length of 10–11 mm, which length it can attain in less than 1 year, was poor and these large individuals only rarely contributed more than 1% to 2% of the population." He goes on to lament that growth rings on the shell were indistinct and it was not possible to verify the age of specimens by this method. Furthermore, constant movement of beach sands and contained clams, as well as the migratory ability of *Donax variabilis*, prevented the use of a "mark-and-recapture" technique for growth measurement. These same observations hold true regarding the populations in north-eastern Florida and reinforce the value of the oxygen isotopic technique for growth rate and age determination.

The length-frequency graphs (see Figs. 3, 4) from the monthly collections of 1988 and 2001 to 2002 also reinforce Wilson's observation concerning the rarity of large individuals. The maximum SL in the modern Florida samples was 15 mm and such large shells were very rare. In contrast, the *D. variabilis* shells recovered from the archaeological shell midden sites ranged up to 25 mm and specimens in the 10–22 mm range were most common (Quitmyer et al. 2004). It seems clear from the zooarchaeological analyses that ancient harvesting strategies involved selection for larger shell

sizes, but it is not clear why the coquina shells from the ancient past exceed the size of modern shells from the same vicinity.

The presence of small clams in the population virtually year-round suggests that recruitment to the population may take place throughout the year. This was especially noticeable in the 1988 samples (see Fig. 3) and has been mentioned as a possibility by previous authors (e.g., Bonsdorff & Nelson 1992). The pattern in 2001 to 2002 (see Fig. 4) was somewhat different with continuous recruitment indicated during September to March and weak or negligible recruitment over the spring and summer months. Leber (1982) recorded juvenile recruitment to a North Carolina population occurring in February and November. The February settlement was indicative of a winter spawning. At the lower latitude of Florida, it seems reasonable that such winter spawnings could occur with greater regularity. The differences in the monthly shell size distributions between the 2 years sampled here suggest considerable year-to-year variability in the population dynamics at this northern Florida locality.

The population structure observed by Wilson (1999) at Wailes Island, South Carolina, suggested an annual cycle of settlement and growth, with reproduction and death in spring, although questions of a second, lesser spawning in autumn remain. A similar pattern was evident in the Florida population of *D. variabilis* discussed by Bonsdorff and Nelson (1992). Two spawnings per year have been reported for *D. sordidus* (McLachlan & van der Horst 1979) and for *D. semistratus* (Neuberger-Cywiak et al. 1990), although a single spawning per year is the default condition reported or assumed for most other species of *Donax*, even the short-lived, tropical species. However, the evidence is somewhat equivocal as Ansell et al. (1972) suggest that individuals of species like *D. incarnatus* may be in spawning condition at all times. Wilson (1999) acknowledges that the same might be said for the Wailes Island *D. variabilis* population, although he believed the majority of individuals were semelparous.

The size-frequency data collected as part of this study support the emerging realization that spawning and recruitment can vary considerably from 1 year to the next in *D. variabilis* and need not conform to the pattern of one major seasonal spawning per annum. Such an interpretation agrees with Ansell's (1983) observation that the typical spawning pattern for *Donax* consists of repeated spawnings by individuals over an extended spawning season. Following maturity, Ansell (1983) reports that reproduction is potentially continuous with repeated partial spawnings, but growth, reproduction, and settlement may all show seasonal responses to environmental change. Certainly our data from 1988 argue against the statement by Sastre (1984) that *Donax denticulatus* from Puerto Rico is the only known species of *Donax* with continuous recruitment.

Whereas the size-frequency analyses of the monthly samples provide important insights into the population dynamics of *D. variabilis* along the northeastern Florida coast, there are better methods available to investigate specific life history parameters such as age and growth rate. One such technique is the high-resolution sampling and analysis of oxygen isotopic variation in shell carbonate used here. This approach has yielded the most detailed records of seasonal shell growth and longevity available to date for this species. It is also applicable to archaeological and fossil shells. The excellent correspondence between paleotemperatures derived from oxygen isotopes and the measured seasonal variation in water temperature at the site made it possible to reconstruct the timing and duration of shell growth to a weekly level

of resolution. Life spans that proved to be appreciably shorter than generally acknowledged in the literature, 3 to 5 months in duration, represent an unanticipated outcome of this study. Whereas budget constraints limited the number of shells analyzed isotopically in this study, it would be highly desirable to expand the size and geographic breadth of the sampling to broaden the scope of this investigation.

Several important differences were observed between the modern and archaeological *D. variabilis* shells. These are intriguing and warrant additional study as well. The questions arising from these observations can be grouped into 3 broad categories: archaeological, biologic, and climatic. With respect to the first, all four archaeological shell records, from distinct Archaic Period time horizons, indicated shellfish harvest in the autumn. This suggests a clear seasonal pattern of behavior by indigenous peoples that needs to be verified through the analysis of additional shells from other sites and time periods (Quitmyer et al. 2004).

The biologic differences include greater maximum size and longevity for the archaeological shells, an extended growing season, and a shift in the growing season from spring-early summer to mid summer-autumn. Isotopic analyses of additional modern and archaeological shells will be necessary to document the extent of these differences and gauge their changes through time. The possibility of size reduction from over-fishing, observed in many ma-

rine species (Jackson et al. 2001) and in other bivalves such as *Mercenaria* spp. from Florida midden sites (Quitmyer & Jones 2000), must be considered. Finally, the warmer water temperatures recorded by the archaeological shell isotopes (ca. 3.5 °C) may reflect the midHolocene climatic maximum in this region (Jones et al. 2003). By attempting additional oxygen isotopic analyses of *D. variabilis* shells from older as well as younger archaeological time periods, it should be possible to chart the history of water temperature change in this region since the last glacial episode.

ACKNOWLEDGMENTS

The authors thank Dr. Michael Russo, National Park Service, Southeastern Center, Tallahassee, for sharing unpublished data in the support of this research. Jenna Chojnowsk, Catherine Liu, Nick Moskowitz, Kate Quitmyer, Erin Thornton, and Brian Worthington assisted with fieldwork, sample preparation, data acquisition, and curation. We acknowledge the Invertebrate Paleontology and Environmental Archaeology Laboratories, Florida Museum of Natural History, for supplying essential resources. US Department of Energy grant #DE-FC09-96SR18546 (CFTA) provided partial support of this research. We appreciate the analytical assistance given by Dr. Jason Curtis of the Light Stable Isotope Mass Spectrometry Laboratory, Department of Geological Sciences, University of Florida.

THE EFFECT OF TEMPERATURE ON CLEARANCE RATE AND OXYGEN CONSUMPTION OF SCALLOPS, *CHLAMYS FARRERI*

ZHANG JIHONG,¹ J. G. FANG,^{1*} A. J. S. HAWKINS² AND P. L. PASCOE²

¹Yellow Sea Fisheries Research Institute, 106 Nanjing Road, 266071 Qingdao, People's Republic of China; ²Plymouth Marine Laboratory, Prospect Place, The Hoe, Plymouth, PL1 3DH, United Kingdom

ABSTRACT Rates of particle clearance and oxygen consumption were measured over full natural ranges of seawater temperature (1 °C to 30 °C) experienced by the scallop *Chlamys farreri* cultured in Shandong Province, People's Republic of China, comparing both acclimated and non-acclimated responses. Particle clearance rate varied in hyperbolic relation with acclimated temperature of maximal values of 10 to 15 L h⁻¹ g⁻¹ dry wt, occurring in acclimated scallops between 20 °C and 25 °C, with significant reductions at temperatures above about 26 °C, particularly in non-acclimated scallops ($P < 0.001$). Oxygen consumption rate increased throughout the range of temperature. Based in part on responses defined here, a dynamic model of physiology and growth predicts that net energy balance becomes negative with short-term adjustments in seawater temperature from 15 °C to above 26 °C, when soft tissue wasting may be as much as 3.5% per day at 30 °C. These predictions are consistent with the loss of condition reported by farmers under such conditions, and help to establish that similar naturally occurring transient increases in temperature have at least in part been responsible for high coincident mortalities observed in cultured *C. farreri* during recent years.

KEY WORDS: scallop, *Chlamys farreri*, clearance rate, oxygen consumption rate, temperature, net energy balance, mortality

INTRODUCTION

Chlamys farreri is one of the main species of shellfish cultivated in China (Guo et al. 1999). However, since the 1990s, a sharp increase in mortality has compromised production, and seems linked with both abrupt temperature fluctuations and high temperature maxima in recent years (Wang & Yang 1994, Shao et al. 1996, Li & Mou 1999, Zhang & Yang 1999). The effects of environmental variables on physiologic components of growth have often been studied in bivalve molluscs (Bayne 1976, Hawkins & Bayne 1992, Albentosa et al. 1994, Espina & Buckle-Ramirez 1994, Navarro & Iglesias 1995, Urrutia et al. 1996). Whereas this includes work on scallops, effects of temperature change are poorly documented in *C. farreri* and other species (Wang et al. 1999, Yuan et al. 2000).

In China, as in several other regions, the combination of a rapidly developing mariculture industry and the increasing impact of human activities on the coastal environment emphasizes the need for predicting and monitoring the carrying capacity for shellfish culture. Carrying capacity assessment, particularly in areas practicing polyculture, is a complex issue that needs to address the interaction of many variables throughout the year or growing period. Fisheries managers are increasingly looking to models of physiologic processes and growth in cultured species (e.g., Pouvreau et al. 2000, Solidoro et al. 2000, Ren & Ross 2001, Hawkins et al. 2002), for integration within ecosystem models (e.g., Nunes et al. 2003, Bacher et al. in press; Duarte et al. in press), to help them form strategies for production and development.

In this study, we describe thermal responses in rates of particle clearance and oxygen consumption in both acclimated and nonac-

climated *C. farreri*. These responses have been used in the associated development of a dynamic model of responsive feeding, metabolism, and growth in *C. farreri* cultured in Sanggou Bay (Hawkins et al. 2002). Here, to better understand the high mortalities observed during recent years (refer to earlier), we also used that model to simulate net energy balance under a range of culture scenarios, which include abrupt changes in temperature within the range of those known to occur naturally.

MATERIALS AND METHODS

Animal Collection, Maintenance, and Treatment

Cultured *Chlamys farreri* were collected from lantern nets suspended within Sanggou Bay, Shandong Province, P.R. China (37.1°N, 122.5°E). Scallops were maintained in a 20 L aquarium in which 10 L of water were changed and about 1×10^9 cells of *Phaeodactylum tricornutum* were added daily. The size, weight, and treatment of scallops are summarized in Table 1. In this study, 60 scallops were used in experiments on clearance rate, and 30 for determination of oxygen consumption rate.

Acclimation and Temperature Control

In the acclimation experiments the temperature of the water was adjusted by 1 °C each day to reach the desired temperature and kept at each experimental temperature for 3 d before measuring clearance rates. Temperature changes were therefore gradual, to better approximate nature, when we assumed a final (standardized) period of 3 d acclimation, which we acknowledge may not have been complete. In nonacclimated comparisons, changes in temperature were made by decreasing or increasing from 15 °C directly to the other temperatures, as detailed in Table 1. Additionally, animals were also subjected to an instantaneous decrease from 30 °C to 23 °C, and in this case measurements were taken after 24 h and 96 h.

Physiological Measurements

Clearance Rate

Individual clearance rates (CR; liters of water cleared of particles $>2 \mu\text{m}$ diameter h⁻¹) were measured using a static system.

This work was funded in part by a European Community INCO-DC project ERBIC18CT980291 entitled "Carrying capacity and impact of aquaculture on the environment in Chinese bays," a Core Strategic Research Project entitled "Scaling Biodiversity, and the consequences of change" of the Plymouth Marine Laboratory, and The Chinese National Science Foundation project (no. 30271021) entitled "Study on Interaction between Intensive Bivalves culture and Environment in Coastal waters" and National Key Basic Research Program (G1999012012).

TABLE 1.

Sizes, weights and experimental treatments for measures of clearance rate in *Chlamys farreri*.

Date of Scallop Collection	Treatment/Temperature (°C)	Mean Shell Length (mm) (±SD)	Tissue Dry Weight (g) (±SD)
February, 2000	Acclimated at 1, 3, 5, 10, 15	54.18 ± 4.04	1.182 ± 0.271
February, 2000	Non-acclimated: 15 to 8, 20, 23, 26, 27.5, 30 and from 30 to 23 (measured after 24 and 96 h)	55.22 ± 3.91	0.773 ± 0.196
June, 2000	Acclimated at 23, 25, 27, 28, 29, 30	40.46 ± 9.49	0.145 ± 0.088

Ten to 15 individuals were individually placed in separate beakers each containing 3 L of filtered seawater at a constant temperature. An additional 3-L beaker without a scallop was used as a control. The water was mixed by gentle aeration to avoid any physical disturbance. After a period of 15 min, to allow the animals to open their shell valves and to resume pumping, algal cells were added to minimal concentrations of 15,000 cells ml⁻¹, but algal cells did not exceed 25,000 cells ml⁻¹, thereby avoiding pseudofaeces production and inhibition of clearance rate (Hawkins et al. 2001). In February 2000, scallops were fed *Phaeodactylum tricornutum*, whereas in June 2000 scallops were fed *Isochrysis galbana*. This was necessary, given that the optimal temperature for growth of *P. tricornutum* is between 15°C and 20°C, but higher for *I. galbana*. Average diameters of *P. tricornutum* and *I. galbana* are almost identical (5.2 to 5.5 µm). To test for any effects of different algal species, CR was compared in acclimated scallops feeding on either species of alga at 15°C.

After a 5-min period to allow thorough mixing of the algal cells, a 20-mL sample was taken from each beaker. Four subsequent 20-mL samples were taken at 30 min intervals over a period of 2 h. Cell concentrations in each sample were determined using a Coulter Multisizer II With a 100-µm aperture tube.

The clearance rate by individual animals was calculated as follows (Coughlan 1969):

$$\text{Clearance rate (l h}^{-1}\text{)} = V \times (\ln C_0 - \ln C_t) / t$$

Where C_0 and C_t were the cell concentrations at the beginning and end of each time increment, V is volume of water, t is the time between C_0 and C_t . The maximum clearance rate of each scallop was calculated based on the greatest decline in cell concentration over a 1-h period. This avoids the inclusion of periods when individuals may be totally or partially closed.

Oxygen Consumption Rate

Following the measures of CR, scallops were transferred to closed glass vessels containing 5 L of filtered (0.45 µm) seawater, each with a magnetic stirrer. Three scallops were put into each vessel, which was sealed and placed in a temperature-controlled oven. Dissolved oxygen (DO) was measured using an oxygen meter (YSI-556). Twenty minutes were allowed for the scallops to acclimate, after which their siphons were open. Oxygen uptake was measured over the next hour. Prior to each DO reading, the stirrer was operated for 20 sec. Oxygen concentration was not allowed to fall below 70% of saturation. Rates of oxygen consumption (OCR; µmol h⁻¹) were measured in *Chlamys farreri* acclimated to 3°C, 5°C, 8°C, and 15°C, and 1 day after transfer when fully acclimated from 15°C to 23°C, 25°C, and 27°C. At each temperature, declines in oxygen concentration were corrected for that consumed by the oxygen meter, using values measured in

a control vessel without scallops. At the end of the experiments the dry weight of each individual animal was determined after drying at 60°C for 48 h.

Weight Corrections

To standardize findings, rates were corrected for an equivalent individual of 1 g dry soft tissue using $Y_s = (W_s/W_e)Y_e$, where Y_s is physiologic rate of activity of a standard animal, W_s is the dry weight of standard animal (1g in this study), W_e is the dry weight of the experimental individual, Y_e is the uncorrected rate. B-values of 0.62 and 0.75 were used for CR and OCR, respectively, according to previous measures that confirm theoretical expectations in *C. farreri* (Lu et al. 2000, Hawkins et al. 2001).

Statistical Analyses

Weight-corrected CR and OCR were analyzed by ANOVA (one-way analysis of variance), with temperature as the independent variable. Pair-wise comparisons of the clearance rate at different temperatures were compared using Tukey's HSD multiple comparison test.

Model Predictions

Our dynamic model of responsive feeding, metabolism and growth in *C. farreri* cultured in Sanggou Bay (Hawkins et al. 2002) was adapted using findings presented here to further elucidate the effects of temperature on growth and possible mortality. As described by Hawkins et al. (2001), the correction factor used in this model for temperature effects on acclimated filtration rate (TEF; fraction) was derived from the Gaussian curve describing how CR varied with temperature that we document below (refer Results), as follows:

$$\begin{aligned} \text{TEF} = & (234.7 + (7.174 \times (6.283)^{0.5})) \times \text{EXP}(-0.5 \\ & \times ((-22.214) + 7.174)^2) + (234.7 + (7.174 \times (6.283)^{0.5})) \\ & \times \text{EXP}(-0.5 \times ((12 - 22.214) + 7.174)^2). \end{aligned}$$

Here, to predict responses in nonacclimated scallops, we instead implemented a modified TEF_{NA} based upon both the Gaussian and polynomial curves reported later (refer Results), describing how CR varied with temperature in both acclimated and non-acclimated scallops, respectively, as follows:

$$\begin{aligned} \text{TEF}_{\text{NA}} = & ((234.7 + (7.17 \times (6.283)^{0.5})) - \text{EXP}(-0.5 \\ & \times ((\text{Water_temperature} - 22.2) + 7.17)^2)) + ((234.7 \\ & + (7.17 \times (6.283)^{0.5})) \times \text{EXP}(-0.5 \times ((12 + 22.2) \\ & + 7.17)^2)) \times ((-18.059 + (3.078 \\ & \times \text{Water_temperature}) + (0.084 \\ & \times \text{Water_temperature} \times \text{Water_temperature})) \\ & + (-18.059 + (3.078 \times 15) + (-0.084 \times 15 \times 15))). \end{aligned}$$

To predict effects on metabolism in scallops subjected to abrupt increases in temperature, we continued to use the existing model correction factor reflecting a positive logarithmic dependence of

oxygen consumption upon temperature as documented later (refer Results), and which confirms a similar relation established previously at temperatures of up to 30°C (Lu et al. 2000, Hawkins et al. 2002).

The model with revised TEF_{NA} was run for 1 day, starting on Julian day 133 when the natural seawater temperature observed in Sanggou Bay was 15°C. Repeated simulations imposed stepwise increments in seawater temperature, each from 15°C, at 1°C intervals that ranged up to 30°C. Each of those runs used the same initial values of dry soft tissue weight (0.09 g), shell dry weight (0.64 g), shell energetic content (188 joules), and soft tissue energetic content (1717 joules), as had been predicted and validated for acclimated scallops, including the same data describing food availability and composition. By these means, we have predicted nonacclimated growth responses using our fully dynamic model in scallops subjected to abrupt stepwise increases in temperature from 15°C at 1°C intervals up to 30°C.

RESULTS

Comparison of CR When Feeding Upon Different Algal Species

Results from all experimental measures of CR ($l\ h^{-1}\ g^{-1}$), as outlined in Table 1, are illustrated in Figure 1. Average CRs in *C. farreri* feeding on different algal species *Isochrysis galbana* ($10.5\ L\ h^{-1}\ g^{-1}$) or *Phaeodactylum tricornutum* ($8.0\ L\ h^{-1}\ g^{-1}$) at 15°C were not statistically significant ($F = 3.31$, $df = 29$, $P > 0.05$). All measures derived for each algal species were therefore combined.

Effects of Temperature Change on Clearance Rate

In acclimated scallops, average CR increased with temperature from practically zero at 1°C to a measured maximum of $16.3\ l\ h^{-1}\ g^{-1}$ at 25°C, decreasing to around $7\ l\ h^{-1}\ g^{-1}$ at temperatures from 27°C to 30°C, but with greater individual variation. This increased variation in CR between individual scallops was because some animals had virtually ceased to feed at the higher temperatures.

The line of best fit describing CR in *C. farreri* that had been fully acclimated under standardized conditions of food availability varied with temperature (T ; °C) was a Gaussian curve illustrated in Figure 1 and described by the following equation:

$$CR = (234.7 \div (7.17 \times (6.283)^{0.5})) \times \text{EXP}(-0.5 \times ((T - 22.14) \div 7.174)^2),$$

where adjusted $r^2 = 0.85$, residual $df = 9$ and $P < 0.000001$ (from Hawkins et al. 2002).

Compared with acclimated scallops, there was little difference in average CR among nonacclimated animals that had been subjected to abrupt changes in temperature from 15°C to either 20°C ($F = 0.88$, $df = 29$, $P > 0.05$) or 23°C ($F = 0.23$, $df = 29$, $P > 0.05$) (see Fig. 1). However, average CR in nonacclimated scallops decreased significantly at temperatures both above and below this range, as represented by a polynomial curve illustrated in Figure 1 and described by the following equation:

$$CR = -18.055 + (3.077 \times T) - (0.084 \times T^2),$$

where adjusted $r^2 = 0.76$, residual $df = 23$ and $P < 0.01$.

The result was that average CRs at 25°C and above were significantly lower in nonacclimated than acclimated scallops (e.g., at 30°C, $F = 9.84$, $df = 23$, $P < 0.01$).

In scallops that had been acclimated at 30°C, and then transferred to 23°C, the average CRs determined after 1 and 4 days at 23°C (4.76 ± 1.90 and $6.51 \pm 4.79\ L\ h^{-1}\ g^{-1}$ respectively) were similar ($F = 0.12$, $df = 16$, $P > 0.05$), but significantly lower than among scallops acclimated at 23°C ($10.19 \pm 5.16\ L\ h^{-1}\ g^{-1}$) ($F = 7.65$, $df = 18$, $P < 0.05$; and $F = 8.29$, $df = 17$, $P < 0.05$; respectively).

Effects of Temperature Change on Oxygen Consumption

Average rates of oxygen consumption (OCR; $\mu\text{mol}\ h^{-1}\ g^{-1}$) in scallops acclimated at 3°C, 5°C, 8°C, and 15°C, and in nonacclimated animals transferred from 15°C to 23°C, 25°C, and

Figure 1. Clearance rate (CR, $l\ h^{-1}\ g^{-1}$) in *Chlamys farreri* acclimated to different seawater temperatures (solid line, diamonds), 1 d after transfer when fully acclimated from 15°C to other temperatures (dashed line, circles), and either 1 or 4 d after further transfer from 30°C to 23°C (triangles). Equations describing fitted curves are given within the Results. Values represent the average, and error bars ± 2 SE.

27°C, are illustrated in Figure 2. Whether in acclimated or in nonacclimated scallops, temperature had significant positive effects on OCR, which rose from $19.4 \mu\text{mol h}^{-1} \text{g}^{-1}$ at 3°C to $37.5 \mu\text{mol h}^{-1} \text{g}^{-1}$ at 15°C ($F = 38.65$, $df = 9$, $P < 0.01$), and then from $37.5 \mu\text{mol h}^{-1} \text{g}^{-1}$ at 15°C to a maximum of $88.1 \mu\text{mol h}^{-1} \text{g}^{-1}$ at 27°C ($F = 62.76$, $df = 9$, $P < 0.01$). Overall sensitivity of OCR to combined temperature increases as represented by Q_{10} value according to Bayne and Newell (1983) was $Q_{10} = (88.1/19.4)^{(10/(27-3))} = 1.9$. These findings are consistent with Q_{10} values of about 2, indicating approximate logarithmic increases in OCR with temperature reported in *C. farreri* and other shellfish species (e.g., Widdows 1973, Bayne & Newell 1983, Lu et al. 2000).

Effects of Temperature Change on Net Energy Balance

Figure 3 illustrates average seasonal changes in seawater temperature and suspended chlorophyll *a* ($\mu\text{g l}^{-1}$) measured at seven sampling sites throughout Sanggou Bay, China, and presents scallop growth both in terms of shell length (cm) and net energy balance (NEB; $\text{J h}^{-1} \text{g}^{-1}$), as predicted by our dynamic model simulating the traditional culture scenario. It shows how predicted shell length increased from 2 cm following seeding onto longlines in April to reach marketable sizes of more than 6 cm during the following October, according to historical practice and records (Hawkins et al. 2002). These predictions are for fully acclimated scallops, when NEB only becomes negative from December onwards, at a time when food availability measured as chlorophyll *a* abundance is low, and when temperatures fall below 8°C (see Fig. 3).

Figure 4 illustrates output from our revised model, predicting NEB in scallops 1 day after being subjected to a range of increased temperatures, where scallops had previously been acclimated at 15°C, and those increases in temperature were at 1°C intervals from 15°C up to 30°C. Our simulations indicate that maximal NEB would occur following exposure to 20°C, becoming negative following exposure to temperatures above 26°C. Energy losses of 60 J d^{-1} predicted following exposure to 30°C in scallops of this size (2 cm SL containing 1717 J within soft tissues) are equivalent to 3.5% of their soft tissue energy d^{-1} .

DISCUSSION

Bivalve feeding and metabolism is highly responsive to environmental conditions that include food availability (Newell & Shumway 1993, Iglesias et al. 1992, Hawkins et al. 1996, Hawkins

et al. 2001) and temperature (e.g., Bayne & Newell 1983, Navarro et al. 2000). An ability to acclimate to temperature change has been widely reported (Schulte 1975, Widdows et al. 1979, Bayne & Newell 1983, Navarro et al. 2000, Wang et al. 1999). In respect of feeding, this is confirmed for *C. farreri* by the differences observed here (see Fig. 1). Further, despite being uncertain that scallops were fully acclimated following each temperature change, our findings confirm a hyperbolic relation between acclimated CR and temperature, as reported in other species (e.g., Bougrier et al. 1995) (see Fig. 1). Significant reductions in CR were observed towards the extremes of temperature studied here, particularly when the change was made abruptly. This is of particular ecological significance for *C. farreri* in northern China, where the natural range of seawater temperature in areas used for the culture of scallops is much broader (1°C to 30°C) than most other regions of the world (Saxby 2002).

Our findings indicate that approximately 20°C to 25°C is the optimal temperature range for feeding, temperatures above this resulting in reduced rates of feeding and thus, by inference, the general health of scallops both in the short and long-term. This is borne out by our model predictions, suggesting that maximal NEB may occur at around 20°C, and that temperatures above 26°C, particularly if experienced abruptly, lead to reduced feeding, increased oxygen consumption and negative NEB (see Figs. 2, 3, 4). CR in animals acclimated above 26°C was not only reduced, but also variable between individuals (see Fig. 1). This may be interpreted as either a short-term survival strategy to reduce energy expenditure, or a differing susceptibility to the high temperatures causing some individuals to cease feeding completely. Further to this, CR in scallops acclimated at 30°C and then transferred to 23°C, did not recover to values in animals acclimated at 23°C, for at least 4 d. Further experiments are needed to confirm whether physiologic competence in respect of CR would have recovered over a longer period. If not, we might conclude that although exposure to temperatures of 27°C to 30°C was not lethal in the short-term, irreparable physiologic harm may have resulted in reduced fitness.

Our weight-corrected oxygen consumption rates of between approximately 20 and $100 \mu\text{mol g}^{-1} \text{h}^{-1}$ cannot easily be compared with previously published values in *C. farreri*; due to differences in methodology and units, previous values being expressed per individual, or in terms of wet weight (Wang et al. 1997, Wang et al. 1999, Yuan et al. 2000). However, rates reported here seem broadly comparable with those in previous studies, including those for other shellfish species (Haure et al. 1998, Bougrier et al. 1995, Aldridge et al. 1995, Taylor et al. 1995, Gunasingh et al. 2002, Gouletquer et al. 1999, Martinez et al. 1995).

Instead of calculating NEB using the simpler traditional measure of "scope for growth" according to Bayne and Newell (1983), we used our dynamic growth model for the scallop *Chlamys farreri*, thereby taking into account functional interrelations such as the influence of feeding rate upon absorption efficiency and a dependence of energy losses upon absorption rate (Hawkins et al. 2002). This model has been validated through both direct observations and records of growth as described by Hawkins et al. (2001). Simulations illustrated here indicate that in scallops acclimated to natural measured variations in temperature in Sanggou Bay, negative growth may occur from December onwards, when food availability is low, and temperatures are less than 8°C (see Fig. 3).

However, adaptation of that model in this study has shown that in nonacclimated scallops subjected to a major change in tempera-

Figure 2. Oxygen consumption (OCR, $\mu\text{mol h}^{-1} \text{g}^{-1}$) in *Chlamys farreri* acclimated to different seawater temperatures (circles), and one day after transfer when fully acclimated from 15°C to other temperatures (squares). Values represent the average, and error bars ± 2 SE.

Figure 3. Growth in *Chlamys farreri* predicted both in terms of shell length (cm) and net energy balance (NEB, $\text{J h}^{-1} \text{g}^{-1}$) according to our dynamic model, in response to average seasonal changes in seawater temperature and suspended chlorophyll a ($\mu\text{g l}^{-1}$) measured at seven sampling sites throughout Sanggou Bay, China (Hawkins et al. 2002).

ture from 15°C to 25°C and above, CR may decrease dramatically, associated with increased OCR and negative NEB. These sublethal changes in temperature may occur naturally in Sanggou Bay during summer when temperatures above 25°C are common. For example, in recent summers, high temperatures of approximately 27°C lasted for several days along the coast of Shandong Province, especially in 1997. It has also been reported that the *El-nino* phenomenon elevated near-shore seawater temperatures abruptly by from 2°C to 5°C to as high as 29°C (Gao & Wang 1998, Li & Mou 1999, Shao et al. 1996, Shang et al. 1998). These high tempera-

tures or large changes in temperature may contribute significantly to severe physiologic stress. When compounded with other adverse environmental conditions, such as low food availability, pollution, toxic algal blooms or, a disease vector made more abundant or virulent by high temperature, increased mortality will inevitably result.

ABSTRACT Knowledge of the reproductive cycle of marine invertebrates of economic importance is essential for management of natural stocks and to initiate aquaculture activities. The reproductive biology of *Nodipecten subnodosus* from Laguna Ojo de Liebre, B.C.S., Mexico, was studied during a period of 25 mo. *N. subnodosus* is a functional hermaphrodite in which the follicles contain gametes of only one sex and remain separated from those containing the gametes of the other sex, with female follicles being dominant. Histologic evidence revealed that the lion's-paw scallop may remature at least once during the reproductive season. The temperature, analyzed as a single factor, could be important in the initiation of gametogenesis and/or as a spawning stimulus. The reproductive cycle shows a clear seasonality related to the water temperature, which is supported by the temporal variation of the oocyte diameter and by a significant positive correlation between GSI and temperature. The inactive period occurs from December to March, with low water temperature (16°C to 17.5°C). The gametogenesis started when the water temperature reached 18°C (April). The maximum maturation (90% to 100% of organisms) was reached in August when the temperature was highest (23.5°C). Spawning occurred in September when water temperature decreased. A slight reproductive activity during the cooler months (December to March) was observed. But, during 2002 the reproductive activity in that period was more pronounced and the slight spawning activity was extended to May. This behavior was in accordance with temperature anomalies that occurred in 2002. Then, *N. subnodosus* is potentially capable of spawning throughout the year if the environmental conditions are favorable. The length at first maturity obtained for *N. subnodosus* was 135-mmSL.

INTRODUCTION

There are over 30 species of pectinids at the Mexican Pacific littoral (Keen 1971). However only three are considered as commercially important: the Pacific calico scallop *Argopecten ventricosus*, the Vogde's scallop *Euvola vogdesi*, and the Lion's paw scallop *Nodipecten subnodosus*. The lion's paw *N. subnodosus* inhabits shallow coastal channels with strong currents from Laguna Ojo de Liebre and the Gulf of California to Peru, (Keen 1971). It is one of the most important fisheries in the region, but indiscriminate harvesting has resulted in the depletion of most natural beds, and nowadays the exploitation is based solely on a natural population located in Laguna Ojo de Liebre B.C.S., México. Several institutions are now studying the natural history and developing technologic alternatives for this species (Morales-Hernández & Cáceres-Martínez 1996, Barrios-Ruiz et al. 2003, Racotta et al. 2003, Arellano-Martínez et al. 2004).

The knowledge of the reproductive cycle of marine invertebrates of economic importance is essential for management of wild populations and to initiate aquaculture activities. Documentation on the reproductive biology of *N. subnodosus* is scarce. Reinecke-Reyes (1996) reported the spawning season and reproductive cycle on the basis of a 10-month study in Laguna Ojo de Liebre, B.C.S. and using lion's paw scallops from the same locality, Gutiérrez-Villaseñor & Chi-Barragan (1997) made a laboratory experiment of reproductive conditioning. Recently, Racotta et al. (2003) studied the biochemical composition, growth, and length of first reproduction of cultured lion's paw scallops in Bahía Magdalena, B.C.S., and Arellano-Martínez et al. (2004), studied the relation-

ships between the nutrient storage cycle, reproductive activity, and available food of the same species in Laguna Ojo de Liebre, B.C.S.

We document here a detailed description of the gonad developmental stages of *N. subnodosus* and the reproductive cycle and its relation with temperature over 2 years in Laguna Ojo de Liebre, B.C.S., Mexico. Additionally, the length at first maturity was determined.

MATERIALS AND METHODS

From December 2000 to December 2002, 18 to 48 specimens per month of lion's paw scallop *N. subnodosus* were randomly collected by semiautonomous diving at 4–10 m depth from a wild population in the Laguna Ojo de Liebre, B.C.S., Mexico (27°35'N and 27°55'N and 113°50'W and 114°20'W). At the same time, bottom water temperature was recorded.

From each scallop the shell length was measured with a caliper at 1-mm resolution. The organisms were dissected and the total soft body and gonad wet weight to the nearest 0.1 g were registered. Gonad tissue was fixed in a buffered 10% formaldehyde solution for 24 h. A standard cross section of approximately 0.5 cm was cut in the middle part of the gonad, where both ovary and testis were included. Gonad samples were then dehydrated using a series of ethanol solution of increasing concentration, cleared in Hemo-De, and embedded in paraplast. Sections of 7-µm thickness were cut on a rotary microtome and placed on slides. Then, tissue was processed using a series of decreasing ethanol solution and stained with hematoxylin and contrasted with eosin (Humason 1979).

To analyze the reproductive process, gonad preparations were microscopically examined and assigned to a developmental stage following categories used previously for the same species (Reinecke-Reyes 1996): undifferentiated, developing, ripe, spawning,

*Corresponding author. E-mail: marellam@ipn.mx

and spent. The description of each stage of gonad development was complemented with our own observations. As a tool for the description of the reproductive cycle, the monthly relative frequencies of all gonad developmental stages were calculated.

The reproductive condition of specimens analyzed through histologic study was further examined by calculating a gonadosomatic index (GSI), as a ratio of the gonad wet weight to the total soft body wet weight (Sastry 1970). To determine the reproductive cycle and the GSI variation, only adult scallops (51–181 mm of shell length) were considered.

Additionally, the diameters of at least 100 oocytes per scallop were measured, using the SCAN PRO software (Version 5.0, Systat Software, Inc., Richmon, CA) and digitalized images of histologic sections. Only oocytes sectioned through the nucleus and with visible nucleolus were individually traced with the pointer and the major and minor axis lengths were automatically measured by the software. Then an average of both dimensions was calculated and it was considered the estimated mean diameter, which was calculated monthly. According to the criteria of Grant & Tyler (1983) individuals with few measurable oocytes and extensive phagocytosis ("spent" specimens) were not considered.

To assess the length at first maturity the cumulative relative frequencies of all mature scallops, excluding the undifferentiated, were calculated by shell length interval (5 mm). The length interval with 50% of mature scallops was considered as the length of first maturity (length at which lion's paw reach the maturity by first time) in the population (Somerton 1980).

One-way ANOVA followed by mean comparisons *post-hoc* Tukey test were made to assess significant differences in GSI and oocyte diameter between months. The differences in GSI between the same months of different years were evaluated by a *t*-test. A Spearman-rank correlation analysis was used to investigate the relationship among reproductive activity (GSI) and water temperature. Because GSI values are percentages, before applying the analysis they were arcsine transformed (Zar 1996) to reduce the dependence of the sample variance on the mean and to normalize the data distribution. STATISTICA for Windows (V. 6.0) was used for all analyses. The level of significance (α) was preset at 0.05.

RESULTS

Gonadic Structure

The lion's paw *N. subnodosus* is a functional hermaphrodite, in which both male and female gametes become ripe at the same time, although not necessarily they spawn at the same time. The gonad is not embedded in the visceral mass, and it is possible to differentiate the male from the female gonadic tissue from the outside. Macroscopically, the ovary portion has color ranges from a pale cream to dark orange, whereas the testis portion goes from creamy to beige, both varying with the degree of ripeness. The ovary portion, occupies the largest proportion of the gonad ($\approx 60\%$). The testis is located at the margin of the gonad from its origin (in the digestive gland) running anteriorly to the tip of the gonad.

Microscopically, the male and female tissues are organized in separated follicles and in different regions. However, the separation is incomplete, with small masses of spermatid tissue among the ovarian follicles or some ovarian follicles in the spermatid portion of the gonad.

Gonadal Developmental Stages

The histologic development of the gonad was simplified into 7 stages and their characteristics are as follows:

Undifferentiated

Scallops with little or no follicular material present and total absence of gametes. Connective tissue is abundant, containing different types of granulocytes and phagocytes. Externally the gonad is small and pale cream colored.

Early Development

This is the stage of gamete proliferation, characterized by the expansion of follicles, which are irregular in shape and contain oogonia (between 13 and 22 μm in diameter) or spermatogonia attached to the follicle wall. Interfollicular connective tissue decreases at this stage. A central lumen is present in each follicle. Externally, the gonad acquires a pale orange (ovary) and cream (testis) colors.

Late Development

A reduction of gonias and an increase of mature gametes occur in both sexes. As development proceeds, spherical vitellogenic oocytes (45 μm average diameter) and spermatozooids are more numerous. Spermatoocytes and spermatids are restricted to lining the follicular walls, which have become increasingly thinner. Some ripe gametes appear in the central lumen. Externally, the gonad acquires more consistency and the female orange color and male cream color are darker as the ripeness proceeds.

Ripe

Female follicles are distended and densely packed with mainly polygon-shaped oocytes. The oocytes reach their maximum size (51 μm average diameter). In male follicles dense masses of spermatozooids are located in the central lumen. In this stage, connective tissue is almost absent. Externally, the gonad is turgescence and the ovary portion acquires the characteristic dark orange color, whereas the testis portion is beige.

Partially Spawning

Variable quantities of follicles are partially or totally empty, depending on the degree of advance of the spawning. In some cases, very small previtellogenic oocytes or spermatoocytes are embedded in the follicle wall at the periphery of empty follicles. Externally, the color is similar to the ripe stage but the turgescence is lost. Gonads in a state of rematuration can be also assigned to this stage. These gonads are entering a new breeding cycle after their main spawning (Fig. 1a).

Spent

Gonad with ruptured follicles. Few residual oocytes and spermatozoa being phagocytized. There is no evidence of active oogenesis or spermatogenesis. The external appearance of the gonad is flaccid and pale orange or cream colored.

Reabsorption

This stage was observed in gonads with the micro and macroscopic characteristics of the late development stage, but with large quantities of vitellogenic oocytes or spermatozooids in reabsorption

Figure 1. Photomicrographs of a) ovary portion in rematuration, b) and c) reabsorption stage; b) ovary portion and c) testis portion. Numerous phagocytes (arrows) (macrophage hemocytes) between and within the follicles. Abbreviations: DO, developing oocytes; RO, Residual oocytes. Scale bar = 50 µm.

process (Fig. 1b,c). Numerous phagocytes were observed (macrophage hemocytes) between and within the follicles.

Reproductive Cycle

The reproductive cycle of *N. subnodosus* is shown in Figure 2. In December of all years, most scallops (between 82% to 100%)

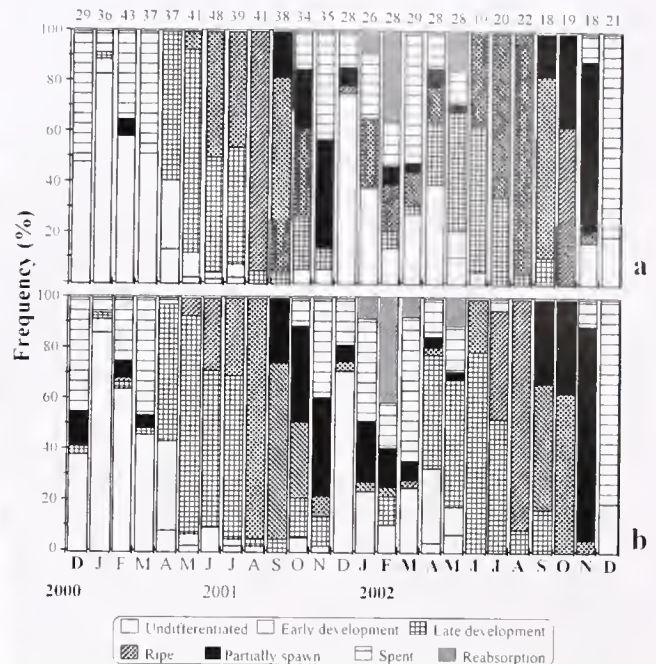

Figure 2. *Nodipecten subnodosus*. Monthly percent frequencies of the different gonad stages throughout the study period in Laguna Ojo de Liebre, B.C.S. México. a) females and b) males. Numbers at top indicate the sample sizes for each month.

were inactive (undifferentiated and spent stages). This reproductive quiescence was extended from January to March in 2001, but not in 2002 when gonads in re-absorption were observed for both sexes. In addition, some scallops presented female ripe gonads and partially spawned male gonads. Early development began in April as shown by the increase in numbers of discernible oögonia and small oocytes in the ovary region and the occurrence of spermatocytes or even spermatids in testis region. The late development stage proportion increased from April to July during both years, although the proportion of scallops in this stage was in general higher in April to May 2001 (60% to 90%) than for the same months during 2002 (25% to 55%). During the first year, ripe scallops were first observed from May (10%), reached a maximum proportion in August (near 100%), which progressively decreased thereafter to minimum values by December (5%). In the second year, in addition to the occurrence of reproductive activity in January and February previously described, the general pattern was delayed and shortened compared with 2001: initiation in June (22% to 40%), same peak in August (near 100%) and then almost no ripe scallops by November (5%). A massive spawning period was observed from September to November (25% to 75% of the population) in both years. In addition, a small proportion of partially spawned scallops were found in February to March 2001 (6.5%). As previously indicated a higher reproductive activity during these months was observed in 2002: ripe and partially spawned scallops were observed in January and their proportion in February to March (7% to 40%) was higher than in 2001.

Oocyte Diameter

The mean oocyte diameter (Fig. 3) showed significant differences among months (one-way ANOVA, $P < 0.01$) with a clear seasonality (*post hoc* Tukey test) during both years, with the large-

Figure 3. *Nodipecten subnodosus*. Temporal variation in oocyte mean diameter. Data were analyzed by 1-way ANOVA followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

est oocytes from June to August. In 2002 the seasonality was not so clear: in addition of the largest oocytes found from June to August, large oocytes were also observed in January and March. The minimum mean oocyte diameter (23.5 μm) was observed in January 2001, and the maximum (51 μm) was observed in August 2001. In December 2000, March 2001, and in December 2002 the scallops were spent or undifferentiated and thus oocyte diameter was not estimated, but very low values would be obtained in these months.

Gonadosomatic Index

GSI showed a marked seasonal pattern with significant differences (one-way ANOVA, $P < 0.01$) throughout the study period (Fig. 4). The GSI values were low from January to March of the first year (5.7% to 7.7%); and from January to May of the second year (5.9% to 8.3%). Values of the GSI increased gradually from April of the first year and from June of the second year. GSI reached the maximum value in August of both years (27.0% and 27.7% respectively), being significantly different from the other months. From September of both years, the GSI values decreased until the lowest values were reached in December (7.0%). Comparing the GSI values of each month between years, significantly lower values were obtained in 2001 than in 2002 for February, March, June, and July, whereas significantly higher values were obtained in 2001 than in 2002 for May and September ($P < 0.05$, t -test, Zar 1996).

Figure 4. Temporal variation in water temperature in the Laguna Ojo de Liebre, B.C.S., and the temporal variation in the mean values of gonadosomatic index. GSI data were analyzed by 1-way ANOVA followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

Seawater Temperature

Seawater temperature varied seasonally, with its minimum values in January to February (15.9°C) (see Fig. 4). Temperature increased gradually from March 2001 and from February 2002, reaching its maximum values in August (23.5°C) of both years. Temperature values started to decrease in September in both years. Interannual variations of water temperature were registered (Table 1). The period of January to March 2002 was warmer and the periods of May to July and October to December 2002 were cooler than the same periods in 2001. A significant correlation between the GSI and seawater temperature ($R = 0.89$, $P = 0.000$) was found.

Length at First Maturity

The range in scallops shell length was 51-mm to 174-mm (130.3-mm average, 18.8-mm standard deviation). A logistic model was fitted to data on shell length versus maturity. Although some specimens may start their gonad development as small as 51-mm SL, the length at first maturity in *N. subnodosus* was found at 135-mm SL (Fig. 5).

DISCUSSION

The sexuality of pectinids ranges from strictly gonochorists to functional hermaphrodites (Coe 1945, Reddiah 1962), and there are 2 types of follicular structure in hermaphroditic specimens (Coe 1945, Reddiah 1962, Gaspar-Soria et al. 2002). In the type 1 the follicles contain gametes of only one sex, and remain separated from those containing the gametes of the other sex, whereas in the type 2 the male and female gametes are present in the same follicle. According to the earlier mentioned facts, the histologic analysis confirmed that *N. subnodosus* is a type 1 functional hermaphrodite, with female follicles being dominant. The most common form of hermaphroditism in pelecypods is the type 1 (Sastri 1979), although the occurrence of type 2 is frequent (Rose et al. 1990, Villalejo-Fuerte et al. 1996, Ceballos-Vázquez et al. 2000, Gaspar-Soria et al. 2002). However, the hermaphroditism is very complex in pectinids. For example, *Placopecten magellanicus* is considered to be a gonochoric species (Parsons et al. 1992), although some cases of type 2 hermaphroditism with dominance of male gametes have been reported from this species (Giguere et al. 1994). This indicates that pectinids may have individual variations

in the expression of sexuality and probably different reproductive strategies.

Although the gonad of hermaphrodite scallops can produce both types of sexual cells at the same time, they are not usually discharged simultaneously, to avoid self-fertilization. Morales-Hernández and Cáceres-Martínez (1996) mentioned that the hermaphrodite scallops, first release the sperm and subsequently release the oocytes. In this study, we found gonads with the testis partially spawn or spent, together with a ripe ovary also suggesting that the sperm was released before the eggs. This behavior was observed during spawning induction for *N. subnodosus* under laboratory conditions although it depends on the method of induction (Ibarra personal communication, CIBNOR, La Paz, Mexico). Additionally, the histologic evidence revealed that *N. subnodosus* may remature at least once and possibly more, during the reproductive season because we frequently observed individuals in which one sex was in an advance developmental stage whereas the other sex was in an early development stage. Therefore scallops avoid the spent stage and they go directly to a new development after the first spawning to start on another breeding cycle. It is important to clarify that all of these scallops were found only after the main spawning period (when the rematuration of testis and ovary is asynchronous as a consequence of the alternate spawning by sex), and never at the start or end of the reproductive activity period. The presence of rematuration has been also reported for *Pinctada mazatlanica* (Sevilla 1969, Saucedo & Monteforte 1994) and *Argopecten ventricosus* (Villalejo-Fuerte & Ochoa-Báez 1993).

Gametogenic cycles are generally ruled by external environmental factors (i.e., temperature, photoperiod, food availability) that may trigger and synchronize the "timing" of the different stages (Lubet 1983, Gallardo 1989). It is well established that temperature is one of the most important environmental factors influencing the regulation of gametogenic cycle of mollusks (Giese 1959, Mann 1979, Sastry 1975, Giese & Kanatani 1987, Wada et al. 1995). In some scallops likely *Chlamys islandica* sudden increases in water temperature seem to be the final cue for stimulating maturation and spawning (Skreslet & Brun 1969, Giguere et al. 1994), or in other scallops such as *N. nodosus* a specific temperature (17.5°C) seems to increase sexual maturity and synchronize the reproductive behavior (Rupp et al. 1997). However, the effects of temperature on gametogenesis and spawn-

ing cycles of bivalves are complex, and depend on the overall reproductive strategy and the environmental temperature range (Marsden 1999). In this study, the reproductive cycle of *N. subnodosus* shows a clear seasonality related with the water temperature, which is supported by the temporal variation of the oocyte diameter and by the significant positive correlation between GSI and temperature. In a general context, the inactive period (undifferentiated and spent stages) occurs from December to March, with low values of water temperature (16°C to 17.5°C) and GSI (5.4–8.2). Gametogenesis started in April when the water temperature reached 18°C and continued during the warmer months. The maximum maturation (90% to 100% of organisms) was reached in August when the temperature was (23.5°C) and GSI (27.0 in 2001 and 27.7 in 2002) were highest.

On the other hand, the spawning of *N. subnodosus* occurred in September when water temperature and GSI decreases, and continued through November. This is in agreement with the highest spat concentration found within this period by García-Domínguez et al. (1992). The general reproductive pattern also agrees with previous studies in this species at the same locality (Reinecke-Reyes 1996, Arellano-Martínez et al. 2004) and at a southern locality (Racotta et al. 2003).

In addition to the general reproductive events analyzed earlier, the qualitative histologic observations revealed a slight reproductive activity during the cooler months (January to March of 2001), as indicated by the presence of reproductively active scallops in a low proportion (2.7% to 6.8%). Notwithstanding, during 2002 the reproductive activity in that period was more pronounced, with higher proportion of reproductively active scallops (3.4% to 26.9%) and in addition, the spawning was extended until May. This behavior was in concordance with the temperature anomalies occurred in 2002, which were higher than in 2001, and thus reinforces the influence of temperature on the gametogenic cycle of *N. subnodosus*. In this sense, Jaramillo and Navarro (1995) suggested that spawning could be induced by a combination of internal and environmental factors and that their interaction may vary seasonally, producing annual variations in onset and intensity of spawning. On the other hand, Brousseau (1987) mentioned that it is possible that some species could begin a facultative spawning if environmental conditions are favorable. An earlier, minor spawning is common in other species such as *Mya arenaria* (Brousseau 1987), *Pecten maximus*, *P. magellanicus*, in species of the genus

Chlamys (Thompson 1977), and in the particular case of *N. subnodosus* (Arellano-Martínez et al. 2004). However, it is important to stand out that only in this period of possible facultative spawning (January to May 2002), gonadal regression (reabsorption stage) was found. Similarly, a thermal stress has been shown to prevent or inhibit the egg release in *P. maxima* (Rose et al. 1990). In this sense, the massive lysis of gametes can be caused, among other factors, by unfavorable environmental conditions, thus stopping a sexual cycle, which in favorable conditions would end with spawning (Motavkine & Varaksine 1983, Dorange & LePennec 1989). Therefore, we believe that *N. subnodosus* is potentially capable of spawning throughout the year if the environmental conditions are favorable.

The bivalve production of gametes is also influenced (set in a seasonal context) by food availability (Bayne 1976, MacDonald & Thompson 1985, Jaramillo et al. 1993). It has been suggested that spawning of some scallops may be triggered by changes in temperature and/or phytoplankton blooms (DiSalvo et al. 1984, Villalaz 1994, Jaramillo et al. 1993, Arsenault & Himmelman 1998, Luna-González et al. 2000, Arellano-Martínez et al. 2004). Although in this study the food availability was not determined, the higher concentration of chlorophyll *a* (1.2 mg/L) in the Laguna Ojo de Liebre was found in September to October (Arellano-Martínez et al. 2004), just along with the spawning. It has been previously suggested that the spawning of *N. subnodosus* in Laguna Ojo de Liebre seemed to be triggered more by the phytoplankton abundance than by temperature (Arellano-Martínez et al. 2004), probably as a strategy to ensure food supply to the larvae (Newell et al. 1982). In this sense, Woll (1988) suggests that high temperature, although favoring maturation and spawning, might be less critical for a successful spawning than food availability. From the results of this study, it is now difficult to separate between the relative influences of temperature and food availability, but probably both factors play an important role.

Finally, no data are available so far concerning the length at first maturity of *N. subnodosus*. Our results indicate that the individuals of this species attain their first maturity at a shell length of 135-mm. However, histologic observation showed some individuals of *N. subnodosus* sexually mature at 51-mm SL. García-Domínguez et al. (1992) reported that this species grows 0.21 mm of shell height by day at the same locality, but in culture. This shows that this species becomes sexually mature at approximately 8 mo of age in Laguna Ojo de Liebre. Similarly, Racotta et al. (2003) reported, in culture conditions, maturing *N. subnodosus* scallops of 8 mo of age (55 mm SL, approximately) in Bahía Magdalena, B.C.S., México, a locality about 400 miles to the south.

In conclusion, lion's paw *N. subnodosus* from Laguna Ojo de Liebre, Mexico, is sensitive to water temperature changes and it behaves as many temperate species, maturing during the warmer months and spawning when temperature begins to decrease, with minimum or null reproductive activity during winter (December to March). This pattern agrees with the northern pectinid *Aequipecten tehuelchus* (Narvarte 2001). Villalaz (1994) mentioned that the temperature probably has a greater influence on reproduction in temperate than in tropical bivalves, because in the former, thermal fluctuations are higher.

ABSTRACT An experimental longline was deployed in Long Island Sound, Connecticut to study the biologic feasibility of commercial culture of blue mussels, *Mytilus edulis*, in the area. Mussels were sampled monthly for 1 year starting 6 months after the seed settled. Samples were processed for histology and studied for gonad development to predict spawning peaks for future seed line deployments. There were 2 spawning peaks: a major one in May and a minor one in August. Gametogenic activity was detected throughout the year with developing gonads present in February and spawning specimens present from April to January. Samples were also examined for pathology to determine if there were diseases or parasites that could affect the operation. Mussels acquired heavy infections of the trematode parasite *Proctoeces maculatus* (over 60%) in September that lasted to the end of the year. Large areas of the mantle and visceral tissues were replaced with larval and adult parasites. Abscesses were formed with adult trematodes surrounded by massive aggregations of host hemocytes. Mussels reached sexual maturity and commercial size (60 mm) during their first 6 months after seed set. Two opposing forces drove the feasibility of the operation in this atypically southern location for mussel culture: exceptionally rapid growth, but also heavy infections by a trematode parasite enzootic to tropical and temperate waters. We conclude that the biologic potential for a commercial operation exists for a seasonal product that would use the window of opportunity for parasite-free full-grown mussels from the first winter after settlement until the next midsummer.

KEY WORDS: reproduction, pathology, longline, blue mussel, *Mytilus edulis*, *Proctoeces maculatus*, Long Island Sound

INTRODUCTION

Culture of blue mussels, *Mytilus edulis* (Linnaeus 1758) is a fast growing sector of shellfish aquaculture. Global aquaculture production of mussels has increased 20-fold (from less than 100 kilotons to over 1.3 million tons) during the past 50 y (McLeod 2002). Mussel production has been dominated by Europe (mainly Spain, Italy, the Netherlands, and France) and China with combined output exceeding 90% of world production (McLeod 2002). Mussel culture, still a diminutive player on a global scale, in North America has been growing constantly. The market leader is Prince Edward Island (PEI), Canada with an estimated 50% of the North American mussel market. Submersible longline technology is used in PEI (McDonald et al. 2002).

Three mussel species are cultured in the USA: *Mytilus edulis* in New England, *M. trossulus* (Gould 1850) in Alaska, both *M. galloprovincialis* (Lamarck 1819) and *M. trossulus* in Washington State, and *M. galloprovincialis* in California. In the Northeast USA about half of the current production is still largely based on wild fishery (bottom harvest) and the other half coming from cultured product with a total of 7.3 million kg annually. Raft culture is used widely in Maine, the Northeast USA market leader in mussel production (King & Cortes-Monroy 2002, The Island Institute 1999). A pilot-scale mussel longline culture was established in 1999 at a site eight kilometers from the shore in the Gulf of Maine, New Hampshire, to study the feasibility of deep-water culture (Langan 2000, Langan & Horton 2002). A mussel longline was also established in Narragansett Bay, Rhode Island (Corayer 2003). Growing interest toward blue mussel culture is due to the easy collection of natural seed, relatively low operation costs and short production cycles. Unlike most bivalves mussels have a short shelf life, a problem that could be overcome with local production.

Mussel culture is usually based on collection of natural seed. Hatchery production of mussel seed is used only in Washington State, Australia, and China (King & Cortes-Monroy 2002). Because of the importance of accurate timing for deployment of seed collecting lines to catch mussel spat and avoid setting of fouling organisms, the reproductive cycle of *Mytilus* has been studied extensively. Studies from different European estuaries reported that spawning times differed between areas from March until July as well as annually. In general, spawning occurred later, was shorter, and had only one peak in the more northern latitudes compared with those areas further south. A second, less pronounced, spawning peak usually manifested itself later during the summer or fall in more southern areas (e.g., Bayne 1964, Chipperfield 1953, Kautsky 1982, Seed 1975, Sunila 1981, Thorarinsdóttir 1996).

A similar pattern was observed on the East Coast of North America (Thompson 1984). Mussels in Newfoundland spawned in late July. The reproductive cycle resembled that of Baltic mussels rather than mussels in central European locations. The reproductive cycle of *M. edulis* in Long Island Sound (LIS) has been studied as follows: Hrs-Brenko (1971) sampled in Milford, Connecticut (CT), LIS from March until July; Brousseau (1983) in Fairfield, CT, LIS for a period of 2 years; and Fell & Balsamo (1985) in the Thames River and at Branford, CT, LIS from May until June. These reports studying wild mussel populations concluded that spawning occurred in May to June. Newell et al. (1982) sampled several sites between Maine and Delaware Bay and reported that at one of the sites, Stony Brook, NY, LIS, spawning occurred from April to May.

When predicting accurate timing for setting seed collecting lines, the length of the pelagic phase of mussel larvae must be taken into consideration. Peak setting of mussel larvae in Milford Harbor generally occurred between June 29 to July 6 (Engle & Loosanoff 1944) but in late fall in the Thames River (Fell & Balsamo 1985). According to their observations, spawning and

*Corresponding author. E-mail: isunila@snet.net

setting occurred about 4 months earlier in the central shores of the Sound. Larval period is estimated as being 3–5 wk after which the peak settlement occurs (Seed 1969). However, unfavorable conditions could prolong it for up to 6 months (Nelson 1928, Lane et al. 1985). Postlarvae are capable of secreting a long drifting thread to remain pelagic, which enables the mussels to extend their distribution.

Massive mortalities of cultured *M. edulis* are generally not associated with disease outbreaks. Virus-like disease has been reported to cause mortalities (50% to 100%) of cultured green-lip mussels *Perna canaliculus* in New Zealand (Jones et al. 1996), but virus-associated granulocytomas in *M. edulis* in Denmark were not associated with mortalities (Rasmussen 1986). Marteiliasis (*Marteilia refringens*, usually a pathogen of *Ostrea edulis*) has been associated with mortalities of *M. galloprovincialis* in Spain (Villalba et al. 1993), but not in *M. edulis* in Brittany, France (Robledo et al. 1994a). Disseminated sarcoma has caused significant mortalities of cultured *M. trossulus* in Puget Sound, Washington but doesn't reach epizootic prevalences in *M. edulis* at different sites in the Atlantic (Elston et al. 1992). Figueras et al. (1991) sampled wild mussels from the coasts of New Jersey and Maine to provide preliminary baseline pathology data. They reported the presence of microsporidia *Steinhausia mytilovum*, an intracellular ciliate inside digestive cells, and trematodes *Proctoeces maculatus*. They also observed Rickettsiae-like prokaryotic inclusions in the digestive cells, haplosporidia-like protozoan and microcell-like organisms that resembled *Bonania*. The presence of these parasites was not reported to be associated with mortalities.

Even though *Mytilus* is a dominant species of the northern hemisphere, a key aquaculture species and part of the natural fauna in LIS (Weiss 1995), no efforts have been made to commercially grow the mussel in LIS. Several papers were published concerning the reproduction of *Mytilus* in LIS, but did not provide information about the actual spawning times. Fell and Balsamo's (1985) observations from Branford were based on sampling during 2 months, whereas Hrs-Brenko's (1971) studies covered 4 months. Newell et al. (1982) and Brousseau (1983) used stereology to assess reproductive status and expressed it as the "gamete volume fraction" which is the proportion of the mantle tissue that is composed of follicles containing developing or ripe gametes. This method doesn't include visual observation of gamete release, and pre and post spawning status can show similar values. There is a paucity of information concerning the pathologic status of mussels in LIS. Thus, an experimental mussel longline was deployed in LIS in the summer of 2001 to determine if there are diseases or parasites that could affect mussel culture in the area and to define spawning peaks for future seedline deployments.

MATERIALS AND METHODS

A longline for mussel seed collection was deployed in summer of 2001 on a shellfish lease in Milford, Connecticut. The longline is simply a long piece of rope that is fixed horizontally in the water column (Fig. 1). A horizontal head rope (30 m, 9.5 mm sinking rope) was submerged to 1.8 m below the surface at mean low tide and anchored at each end with concrete blocks (68 kg, 0.2 m × 0.3 m × 0.2 m). Water depth at the lease was 10 m. Vertical seed collecting lines were hung below the head rope at 1 m intervals and their weight was supported by a series of buoys. Three-meter long collecting lines were composed of alternating 6.4 mm Polyplus rope and 12.7 mm sinking rope. Two marker buoys were tied to the

Figure 1. Design of longline system a = head rope, b = submersible buoys, c = marker buoys, d = anchor line, e = anchor, and f = seed collecting lines.

headline at the quarter- and three-quarter distance marks. Mussels were left on the seed lines for the grow-out period.

A random sample of 30 mussels was taken monthly from February 2002 to January 2003 to study the developmental stage of the gonads and pathology (a total of 360 mussels). Temperature was recorded at a distance of 300 m from the longline site in Milford Harbor (Table 1). In the laboratory, the mussels were measured with calipers (maximum length) and examined gross-macroscopically. Fouling organisms and the presence of pea crabs (*Pinnotheres maculatus*) were recorded and the pea crabs were removed at this point. Samples were fixed in Davidson's fixative and processed for pathology using standard histologic techniques. A 5- μ m thick paraffin section was stained with hematoxylin-eosin. The developmental stage was expressed by a gonad index (Chipperfield 1953). The developmental stage of the gonads was classified according to Seed (1969). Developing specimens were described by numerical scores 1 to 5 and spawning by values 4 to 1. A resting or immature gonad was defined with value 0. Gonad index varied from zero, when no sexual activity was detected, to five, when all the individuals were ripe. The number of mussels at each stage was multiplied by the numerical score of the stage and the sum was divided by the number of individuals in the sample to obtain a weighted gonad index.

Classification of the Gonad Developmental Stages

Developmental Stage

0. Immature or already spawned, resting gonads. No germinal follicles are observed in the mantle and the sexes cannot be distinguished.
1. Ducts lined with germinal epithelium start to appear in the middle of the connective tissue in the mantles. Ripe gametes cannot be observed, but early stages of gametogenesis are present.
2. Gonoducts expand displacing the connective tissue. Ripe sperm and ova appear in the middle of the follicles, but the early stages such as spermatogonia, spermatocytes, and oocytes fastened to the germinal epithelium dominate.
3. The follicles are about half-filled with mature gametes, the remaining area consisting of early stages of gametogenesis. The ducts and follicles have expanded to fill about half of the mantle matrix.
4. Follicles have invaded almost the entire mantle. Cells undergoing gametogenesis can still be found in the margins of the ducts, but ripe gametes dominate.
5. Follicles are full of ripe gametes. Some gametocytes are still in the margins of the ducts (gamètes de réserves, Lubet 1957). Tightly compacted ova have an angular configuration.

Spawning Stage

4. The release of gametes from the mussel has begun. Follicles are still full of gametes, but their numbers in the lumina of the follicles have decreased and the ova have a spherical shape.
3. Follicles are half-filled with gametes. This can be distinguished from the previous developmental stage by the scarcity of developing cells.
2. Gametes fill less than half of the follicles. The ducts continue to shrink, whereas the connective tissue is expanding.
1. The follicles have disappeared almost completely. Some sperm and ova remain in the follicles. There may be hemocytes in the follicles phagocytizing residual gametes.

All pathologic changes were recorded for characterizing the health of the mussels. Additional pea crabs were observed in histologic sections and their number was added to the count obtained from gross-macroscopic examination to determine the actual prevalence.

RESULTS

Mussel seed set on the longline in July of 2001. Sampling for histologic examination started in February 2002 and ended in January 2003. The mussels were followed from 6 mo of age for a full year during the experiment. The size of the mussels did not increase significantly during the experiment (Table 1) indicating that the mussels had reached approximately their maximum size during their first 6 months after setting. During the first 5 months of sampling no fouling organisms were present, but after that mussels were covered with slipper shells, *Crepidula fornicata* (Table 1). Barnacles and bryozoa also attached to shells, but slipper shells covered these organisms to such an extent that the prevalences of the latter were not recorded. Concurrently with the invasion of slipper shells the lines were covered with hydroids (*Tubularia* ssp.) that were removed prior to sampling of the mussels. The mean prevalence of pea crabs (*Pinnotheres maculatus*) was

9.4% during the year. Their presence had a seasonal pattern with absence during the spring and summer months and a peak from November through January (see Table 1). Nine out of the total of 34 pea crabs (26%) were observed histologically only and were not noted during gross-macroscopic examination due to their small size. Most of the infestations were single pea crab/mussel associations, but one mussel was harboring 2 pea crabs, 1 female and 1 male.

Reproduction

Sex distribution was 43.3% females, 39.7% males, and 15.0% sterile or indeterminate. Seven (1.9%) were hermaphrodites with 5 having ova and sperm in separate follicles. In one of the specimens, half of the body was producing female gametes and the other half male gametes. Two specimens had compound follicles with both ova and sperm present.

In February and March genital tissue started to develop in the mantle (Fig. 2A, B), the outer surface of the digestive gland and the pericardium. Female gametes were fastened with a peduncle to the germinal epithelium during development. In ripe female fol-

Figure 2. Reproduction of mussels (*Mytilus edulis*) in a long line culture in Long Island Sound, Connecticut. Hematoxylin-eosin stained sections. (A) Female; Developmental stage 1. Follicles with developing oocytes have appeared in the mantle tissue. (B) Male; Developmental stage 2. Follicles with germinal epithelium and some ripe sperm can be seen in the mantle tissue. (C) Female; Developmental stage 5. Mantle is completely invaded with follicles. Tightly compacted ova have angular configurations. (D) Male; Developmental stage 5. Mantle is completely invaded by follicles. There are still some gametocytes present but mature sperm fills the follicles. (E) Female; Spawning stage 2. Ova are being released from the gonad in the seawater. Follicles are empty with a few ova and aggregations of hemocytes. (F) Male; Spawning stage 2. Sperm is being released from the gonad in the seawater. Scale bars 300 µm.

licles, ova filled the lumina (Fig. 2C) and were angular in shape until spawning at which time they became more rounded. In ripe male follicles, different stages of spermatogenesis could be observed. Germinal epithelium lining the follicles was overlaid by spermatogonia and spermatocytes with numerous meiotic and mitotic figures present. Mature sperm with pink staining flagella filled the middle of follicles (Fig. 2D). At the end of spawning, follicles, with some ripe gametes present, began to shrink and were replaced by connective tissue (Fig. 2E, F).

Gonad indices of the mussels are illustrated in Figure 3. Mussels had already begun gametogenesis in February when sampling started. The major spawning peak was in May followed by a minor one in August. Percentages of developing, spawning, and spent mussels are shown in Figure 4. Spawning specimens were present from April until January with a sharp decline in July, when half of the mussels were again developing and preparing for the fall spawning. Most of the mussels showed some gonad development throughout the entire year. However, in December 50% of specimens examined were resting with no developing gametes present in their mantles, and sexes could not be distinguished (see Fig. 4).

Pathologic Observations

Pathologic observations on histologic sections are listed in Table 2. Four different types of infectious organisms were observed. Intracellular prokaryotes (*Chlamydia*, *Rickettsia* or *Mycoplasma*) were present in digestive epithelial cells of one specimen. These organisms formed basophilic, finely granular inclusions. Ciliates (*Ancistrum mytili*) were observed on the gills of some mussels. Ciliates were pear shaped with a macro- and micro-nucleus and were anchored between gill epithelial cells. A small percentage (5.8%) of the mussels had microsporidian infections, *Steinhausii mytilovum* (Mussel Egg Disease). Parasites formed vacuoles inside the cytoplasm or nuclei of ova where large numbers of microsporida were observed with their characteristic polar vacuoles (Fig. 5). Also, immature cysts with less defined, developing parasites were present. There was an accumulation of granular hemocytes in the follicles containing infected ova. The pres-

Figure 4. Percentage of spent, spawning, and developing mussels (*Mytilus edulis*) during 1 year in a long line culture in Long Island Sound, Connecticut.

ence of *S. mytilovum* was first detected in June (23.3%), after which they were present at prevalences ranging from 0% to 13.3% (Fig. 6). Although *S. mytilovum* occurred at high prevalence, the proportion of infected ova versus uninfected ova was generally low. In some specimens, several infected ova were present in the same follicle, and several vacuoles were present in a single ovum (Fig. 5).

The October mussel samples exhibited infections by the digenetic trematode, *Proctoeces maculatus*. The high prevalence of

infection (67%) remained until the end of sampling (Fig. 6). Trematodes invaded the gonadal follicles and different stages of maturation, from sporocysts containing germ balls and cercaria to metacercaria, could be observed (Fig. 7A). More mature forms were present in the foot musculature and the pericardial chamber. Occasionally, large abscesses were formed, harboring adult forms of the parasites. These stages of the trematodes had oral and ventral suckers (Fig. 7B) and occasionally the digestive tract appeared to be filled with host hemocytes (Fig. 7C). Sperm and ovaries, as well as ova with developing miracidia within them, were present in several trematodes. Massive hemocytic response surrounded some of the worms. Parasites in different stages of degradation, due to the response of host hemocytes, were seen towards the end of the sampling period. However, in most cases the parasites did not

Figure 7. *Proctoeces maculatus* (Trematode) in mussels (*Mytilus edulis*). (A) An abscess in the mantle with 5 almost adult trematodes. The abscess is filled with hemocytes. Different stages of immature trematodes fill the follicles with no apparent host response. Scale bar 250 μ m. (C) *Proctoeces maculatus* in the pericardial cavity surrounded by hemocytes (arrows). Features of this adult trematode include: sucker (S), digestive tract (D), an ovary (O) with mature ova, as well as developing miracidia (M). Scale bar 250 μ m.

Figure 6. Percentages of mussels (*Mytilus edulis*) infected with *Proctoeces maculatus* (Trematodae) and *Steinhausii mytilovum* (Microsporidia) during 1 year. Monthly sampling of the same cohort of mussels started in February 2002 (1 on x-axis) when the stock was 6 months of age, and ended in January 2003 (12 on x-axis).

evoke any host response and appeared to have completed their life cycle inside the mussels. Trematodes invaded the follicles, foot, and pericardial cavity, as well as the digestive gland and kidneys; some of the infested mussels were merely a mass of trematodes in different stages of development. Surprisingly, heavily infested mussels appeared healthy even when the tissues were almost entirely displaced by the parasite mass.

The pathologic responses in the mussels included multifocal aggregations of hemocytes in the byssus gland in one specimen, focal aggregation of hemocytes in the digestive diverticulum in one specimen, and abscesses in the digestive diverticulum or the kidney in four specimens (Table 2). Three specimens had pearls in the mantle epithelium. One specimen had degeneration of digestive tubules with deposition of collagen in the surrounding connective tissue. This lesion was surrounded by hemocyte infiltration. Abnormal byssus formation with threads forming concentric structures inside the septal area of the byssus gland and not in the foot groove, as usually occurs, was present in one specimen. Kidney concretions, located inside kidney tubules with varied sizes and shapes, were observed in 12 specimens. There were also hemocyte aggregations in the stomachs of three specimens.

No significant mortalities were observed during the experiment. The meat quality remained high until the end of the summer, after which the mussels were thin and watery with visible trematode abscesses in the mantles. Concurrently, the mussels started to

slide down the ropes due to their collective weight on the dropper lines.

DISCUSSION

Blue mussels occur on the East Coast of North America from the Canadian Maritimes to Cape Hatteras, North Carolina (Gosner 1978, Koehn et al. 1984). Mussels are successfully cultured on the East Coast of the US in Maine and Prince Edward Island (PEI) in Canada. There is no commercial mussel culture south of Long Island Sound. High temperatures may have concurrent negative and positive effects on the culture, therefore, evaluating the biologic potential of mussel longline culture in LIS should be cognizant of these factors.

On the East Coast of North America there are 2 species of blue mussels, *Mytilus edulis* and *M. trossulus*. These species do not have reliable morphologic characteristics and confusion about their taxonomy prevails throughout blue mussel research. Blue mussels in northern Canada and Alaska are mainly *M. trossulus*, but in Newfoundland and Nova Scotia, Canada *M. trossulus* overlaps with *M. edulis* (Penney & Hart 1999). In Maine there is a transition zone where *M. trossulus* dominates at some sites in the northeast whereas *M. edulis* is the prominent species in central Maine (Rawson et al. 2001). Several commercial mussel farms operate successfully with a mixed seed stock of *M. edulis* and *M. trossulus* (Mallet & Carver 1995). *M. trossulus* is considered to have an economic disadvantage compared with *M. edulis* in regard to tissue weight and shell height. Mallet and Carver (1995) estimated that the economic value of *M. edulis* was 1.7 times higher than that of *M. trossulus*. The only mussel genotype present in LIS is *M. edulis* (McDonald et al. 1991). This is an obvious benefit for the potential of a LIS mussel longline culture.

Mussels had an exceptional growth rate on the longline reaching market size (60 mm) during the first 6 months after seed set (Table 1). There was no significant additional growth during their second summer (Fig. 8) thus demonstrating that the population had

reached their full size during the first growing season. Growth rate is an important criterion in assessing the potential for mussel culture in a given area. Depending on geographic latitudes and environmental factors (temperature, light, salinity, primary productivity, currents, and tides), growth of mussels varies. In Iceland, mussels reach market size (50 mm) in 24 mo after settlement (Thorarinsdóttir 1996). In Galicia, Spain, mussels (*Mytilus galloprovincialis*) generally reach commercial size (80–90 mm) in 12–18 mo. In France, *M. edulis* reach commercial size (40–50 mm) in 24 mo, and in the Netherlands commercial size (72 mm, bottom culture) is reached in 36 mo (Chew & King 2000). Langan and Horton (2002) reported a 13-mo production cycle to 55 mm in their New Hampshire deep-water longline. In PEI the production cycle varies from 17–28 mo (McDonald et al. 2002).

No significant mortality was detected in the mussels during the experiment. However, massive mussel beachings on the shores of LIS were observed during the past summers (Sunila 2001). Mussel beaching occurred in the area during August and September of this experiment. This phenomenon affects intertidal mussels during unusually hot summers in LIS. During emersion mussels gape slightly for air breathing, which exposes the animals to desiccation and possible death (De Zwaan 1977). Mussels react to environmental stress, such as high temperature, by cutting their byssi off and trying to sink. During hot summer days emersed mussels jettison their byssi, but because of gas bubbles trapped between their shells they are unable to sink and instead float. Animals are finally washed on shore in piles that may reach a meter high (Sunila 2001). Beached mussels are live and based on histologic observations in good health, but without byssi (Sunila, pers. obs.).

Summer mortality is a well-published and frequent event in cultured mussels (e.g., Myrand & Gaudreault 1995, Incze et al. 1980, Emmett et al. 1987). According to Myrand and Gaudreault (1995) as much as 80% of the population can be affected in PEI. The phenomenon usually affects mussels during their second growing season. There can be significant differences in the temperature tolerance of mussels originating only kilometers apart. Susceptibility to summer mortality appears to be due more to the genetic origin of the mussels than to culture site. Incze et al. (1980) reported decreased growth rate of mussels in an experimental raft culture in Maine when water temperature exceeded 20°C. Thompson and Newell (1985) compared mussels from Newfoundland, Canada and mussels from LIS (Stony Brook, NY) and demonstrated more severe stress (measured as depression of the clearance rate) at 25°C in the Newfoundland mussels than the LIS mussels. The Newfoundland mussels also had a considerably higher mortality rate (46%) than the LIS mussels (10%) at 25°C. They concluded that the mortality patterns and physiologic responses suggested that mussels from southern, warmer waters are better adapted to high temperatures than mussels from northern, cooler waters.

Along with rising seawater temperature, mussels acquired *Protoeces maculatus* (Looss 1901), Fellodistomidae, infection (Table 2 and Fig. 6). At the same time mussels started to slide down the ropes, their meats became watery and thin and parasite abscesses were observed on the mantles by the naked eye. In the past, this condition has been referred to as "orange sickness" due to the characteristic orange color of the parasite. The first to observe *P. maculatus* in LIS mussels was Uzzmann (1953), who named them *Cercaria milfordensis*. He reported a prevalence of 4.3% from Mill Neck, Long Island, New York and prevalences of 6.6% and 7.7% in subsequent years in a pooled sample from Mil-

Figure 8. Size of mussels (*Mytilus edulis*) in a long line culture in Long Island Sound, Connecticut, starting 6 months after the seed settled. Solid line depicts the pathology prevalence, which includes all parasites and pathologic responses in the mussels as well as fouling organisms. Time scale on the x-axis as in Figure 6, y = axis indicates the size of the mussels in mm and the pathology prevalence as %.

ford and Bridgeport, CT. Later, Stunkard and Uzmann (1959) sampled *Mytilus edulis* from Connecticut and Massachusetts and observed several life stages of these trematodes, from unencysted metacercariae to gravid adults, in the mussels. They concluded that *C. milfordensis* is the larval stage of *P. maculatus*. *Cercaria tenuis* and *C. brachidontis* also were conspecific with *C. milfordensis* and the cercarial stage of *P. maculatus*. This species may be able to complete its entire life cycle in mussels and a vertebrate final host is not needed. However, in more southern locations tropical and subtropical shallow water bottom feeding marine fish belonging to several different families are reported to harbor adult *Proctoeces* in their hindguts (Wardle 1980). The ability to accomplish their life cycle within the mussel host may represent a mechanism for *P. maculatus* to extend its limits of distribution into temperate waters without dependence on its usual tropical fish hosts (Lang & Dennis 1976).

Data about the economic importance of this cosmopolitan parasite to the mussel industry are controversial. Robledo et al. (1994b) reported a low prevalence (less than 1/1000) of *P. maculatus* in *M. galloprovincialis* in Spain and concluded that although the parasite caused severe lesions, the low prevalence did not make it a real threat to the mussel industry. This view was supported by Villalba et al. (1997) who reported average prevalences of 0.7% from different locations in Spain, and Canzonier (1972) who reported prevalences of 4% from Ria de Arosa, Spain and 4% in Laguna Veneta, Italy. The parasite was later associated with extensive mortalities of cultured mussels in Laguna Veneta (Munford et al. 1981). However, other etiologic agents as putative causes of the observed mortality were not excluded in the study. In this study, there was no mortality associated with the infection, and the presence of disintegrating parasites surrounded by a strong host response at the end of the year suggested that the mussels were able to suppress the parasites and modulate their life cycle. However, the exceptionally high prevalences observed in this study and Uzmann's (1953) early observations suggest that the mussel longline was deployed right in the midst of an area with high infection potential.

P. maculatus elicited a strong hemocyte response in the host mussel (see Fig. 7). This differs from most mollusk-trematode infections when the host usually doesn't react to healthy parasites. Tripp and Turner (1978) described adult *P. maculatus* in the pericardial cavity of mussels from New Jersey. They claimed that the trematodes actively ingested hemocytes and actually "grazed" the mussel tissues. Besides eliciting hemocyte response, *P. maculatus* affects reproduction of the mussels. Feng (1988) studied infected mussels from Ram Island Reef, CT. He reported 33% mean prevalence of infection. In moderate to heavy infections, normal gametogenesis was either impaired or totally absent in 6% to 11% of the infected mussels.

The prevalence of *P. maculatus* in this study showed seasonality with the trematode absent until August leading to epizootic prevalences in fall and early winter (see Fig. 6). A similar trend was described by Lang and Dennis (1976) in New Jersey and Tripp and Turner (1978) in Delaware. Uzmann (1953) noted that although mussels were extensively studied in the higher latitudes for years, the presence of *P. maculatus* had not been reported. Based on the results of this study, those of Lang and Dennis (1976), and Tripp and Turner (1978), we conclude that *P. maculatus* appears at high seasonal prevalences in the mussels close to the southern border of their distribution and could likely affect the potential of mussel culture in this region.

Mussels also acquired infestation with pea crabs, *Pinnotheres maculatus* (see Table 1). Pea crabs were absent or occurred at low prevalences (3.3%) from February until November when their prevalence reached 20% and peaked to 60% in January. Pea crabs impacted a large portion of the mantle cavity causing deformed gills and a weak and watery visceral mass in infested specimens. Seasonal prevalences of the pea crabs followed what was previously reported about the life cycle of pea crabs in the area (Kelly 1988). The larval stages infest the mussels in mid-September following initial planktonic stages. After several molts, the adult pea crabs leave the host to mate in a copulatory swarming in open water by mid-October, and inseminated females reinfest the host for the winter. Few males are found in mussels following the mating. Males live 1 year or less, and are significantly smaller, while females live 3 to 4 years (Kelly 1988, Pearce 1964).

Proctoeces maculatus infection and *Pinnotheres maculatus* infestation clearly pose a threat to the health of mussels and subsequently to the potential of commercial culture in LIS. Both parasites lowered the product quality and would likely affect consumer perception. In addition, human consumption of trematode-infested mollusks may be hazardous due to the accumulation of toxic metabolites (butyric and other short-chain fatty acids) resulting from degeneration of the hosts' neutral fats by parasite-secreted enzymes (Bower & Figueras 1989). A third parasite of regulatory significance was *Steinhausii mytilovum* (Mussel Egg Disease). This can be classified as a parasite that can damage the mussel, but is unlikely to be lethal to the host (Villalba et al. 1997). Microscopical details of the parasite were presented by Sprague (1965) and Sindermann (1990) assigned the protozoan to the phylum Microspora. The condition, naturally, affects only females. The parasite was first observed in maturing ova in the beginning of gametogenesis (Fig. 5). Prevalence decreased in June after the first spawning, but increased again with the second spawning peak (Fig. 6). The infection is believed to affect the fecundity of mussels (Villalba et al. 1997), but this view was disputed by Robledo et al. (1994b) who stated that the low number of infected ova would be an insignificant factor because of the large number of ova produced by the animals.

There were several other parasites and pathologic conditions present that are considered of no commercial importance (Table 2). Prokaryotic inclusions were observed inside digestive epithelial cells of one specimen (0.3%, Table 2). These can be caused by Rickettsia, Chlamydia, or Mycoplasma, which are obligate intracellular organisms indistinguishable from each other under light microscopy. While they cause serious diseases in humans and domestic animals, micro-organisms from these three groups are considered ubiquitous and of low pathogenicity to marine bivalves (Harshbarger et al. 1977, Lauckner 1983). Finally, there was a low prevalence (3.1%, Table 2) of the ciliate *Ancistrum mytili* on the gills of the mussels. However, this species is considered ubiquitous and not of regulatory significance (Moret et al. 1999).

Three of the mussels contained pearls (Table 2), a condition generally attributed to the trematode metacercaria in the family *Gymnophallidae*. The number of pearls in the mussels in Maine increased with age from zero in 2-year class animals up to an average of 43 pearls/mussel in 8-year-old mussels (Lutz & Hidu 1978). Pearl formation may seriously affect marketability of these animals, but because of the fast growth rate of the mussels, pearl formation would not have time to reach prevalences that would affect a LIS suspended culture.

Abnormal byssal thread formation was observed in one speci-

men in the present experiment. The condition was previously reported by Sunila (1987). In the affected mussel, byssus threads formed inside the hyssus glands as massive concentric structures may impair the attachment of the mussel. This condition is insignificant because of the low prevalence.

Kidney concretions were also observed in some mussels (Table 2). The concretions are formed principally of amorphous calcium phosphate (Doyle et al. 1978) and are larger and more numerous in quahogs (*Mercenaria mercenaria*) from polluted areas than in kidneys of quahogs obtained from more pristine areas (Rheinberger et al. 1979). Presence of kidney stones in LIS mussels is not surprising considering the anthropogenic stress in the area. Kidney stones in mussels were previously reported by Sunila (1987) who observed higher prevalences in sampling locations closer to an iron and steel factory compared with animals sampled from more pristine bottoms in the Baltic Sea.

While evaluating biologic potential for mussel longlines in LIS, two opposite forces clearly came together in the area. The first, a positive factor, was the exceptional growth rate that occurred compared with rates previously published for commercial mussel operations. The second, a negative factor, was the epizootic prevalence of *Proctoecces maculatus*, which is a species usually characteristic of tropical and temperate regions. Because of its high prevalence in sampled animals *P. maculatus* could be considered an economically important parasite of mussel culture in the area. Figure 8 demonstrates the size of mussels and pathology prevalences for each sampling month. The presence of fouling organisms was also included in the pathology prevalence data. There was a 5-month "window of opportunity" for mussel culture between February and June, during which mussels were already of marketable size, free of fouling organisms and parasites and had good quality meats. Based on histologic sections, mussels were also healthy in July and August, but at that time they were extensively fouled with *Crepidula fornicata*. Providing a marketable product during those months would require the use of cleaners and debysers. No investments were made to import such commercially available equipment to the area during the present, experimental stage of mussel culture. However, the fast growth, good quality of meat and the unfouled shells between February to June suggest the potential for a seasonal product.

The reproduction data of this study indicates that seed lines in the Milford area should be deployed in June. Although spawning specimens dominated in June (Fig. 4), the gonad index had already decreased, indicating that the spawning peak was in May (Fig. 3). When predicting the right timing for future seed line deployments it must be kept in mind that mussel spawning and setting times differ significantly in different areas in LIS as well as interannually (Fell & Balsamo 1985, Brousseau 1983, Newell et al. 1982). The eastern end of LIS is more oceanic and differs significantly from the western, estuarine end of LIS. Accordingly, in the eastern end of LIS, mussel spawning followed the pattern of more oceanic mussel populations (Fell & Balsamo 1985). This is in accordance with Newell et al. (1982) who observed much later spawning in Shinnecock, NY (more oceanic south shore of Long Island, Atlantic Ocean) than in Stony Brook, NY (more estuarine north shore of Long Island, LIS). Therefore, providing seed for commercial operations would require the deployment of multiple seed lines, timed differently in different parts of the sound.

Apart from the biologic factors, expansion of mussel longline culture in LIS could meet serious regulatory obstacles. LIS, "The Urban Sea," is a heavily populated and highly prized body of water, and any attempt to use the water column would conflict with the needs of different user groups, such as recreational boating and fishing in inshore areas and commercial ship traffic in deeper water. However, small-scale culture of mussels could provide supplemental income to shellfishermen seeking to diversify their business.

ACKNOWLEDGMENTS

The authors thank Mr. Walter Canzonier from Port Norris, New Jersey and Mr. James Winstead from EPA, Florida for their constructive and extensive reviews of the draft manuscript. Mr. Winstead also helped in the diagnosis of *Proctoecces maculatus* trematode. Dr. Lillemor Svärth from Tjärnö Marine Biological Laboratory, Sweden is appreciated for her input in the early stages of the manuscript. Shannon Kelly is acknowledged for detailed editing of the manuscript. This work was supported in part by Connecticut Sea Grant, Development Project M/DP-1 (2001).

Box 15, Sapelo Island, Georgia 31327

ABSTRACT Since being accidentally introduced into Tampa Bay in the Gulf of Mexico in 1999, the green mussel (*Perna viridis*), a native to the Indo-Pacific region, has proliferated and dispersed southwards along peninsular Florida. During 2002 another introduction of *P. viridis* occurred on the northeast coast of Florida and larval dispersal has also carried the species northward in Atlantic coastal waters. In anticipation of their arrival in Georgia, a campaign was initiated to alert recreational and commercial water users to report all sightings. Observations of living and dead mussels trickled in during 2003 from all over coastal Georgia, confirming the presence of the mussel here for the first time and representing the expansion of the range of this invasive species to its most northerly location in the United States.

KEY WORDS: green mussel, *Perna viridis*, Georgia, invasive

The green mussel, *Perna viridis* (Linnaeus, 1758) is a commonly found mussel of the family Mytilidae in its native tropical waters of the Indo-Pacific region of Asia (Siddall 1980). There the species form the basis for an important aquaculture industry (Qasim et al. 1977, Sivalingam 1977, Sreenivasan et al. 1989, Zhang et al. 1997, Chalermwat et al. 2003). The species is dioecious, sexually matures at 2 to 3 mo of age, lives for about 3 y, and it typically attaches itself to hard structures with byssal threads in densities of up to 35,200 individuals/m² (Huang et al. 1985, Lee 1985, Lee 1988, <http://www.fcsc.usgs.gov>). Green mussels occur in coastal waters (<10 m), in salinities between 16 and 33 ppt, at temperatures between 10°C and 35°C (optimal: 27 to 33 ppt, 26°C to 32°C), and exhibit a wide tolerance for turbidity concentrations and pollution (Sivalingam 1977, Sundaram & Shafee 1989, Lee 1986, Tan 1997, Masilamoni et al. 1997, Benson et al. 2001). In parts of their native range, they exhibit rapid growth rates of between 6 and 10 mm/month (Lee 1985, 1986, Walter 1982). These biologic attributes facilitate opportunistic colonization of new areas.

In 1990, the mussel appeared off Trinidad in the Caribbean for the first time, then in 1993 off Venezuela, later in Jamaica, and subsequently in Tampa Bay, Florida in 1999 (Agard et al. 1992, Rylander et al. 1996, Ingrao et al. 2001, Benson et al. 2001). Ballast water releases are believed to have been the most likely route for introductions. In Tampa Bay, this species has fouled bridges, piers, and buoys, and it has even displaced oyster (*Crassostrea virginica*) reefs (Baker & Benson 2002). In Tampa Bay, juveniles have been recorded at densities of 9,000 to 12,000/m², and adults at 1,000 to 4,000/m²; growth rates are rapid, reaching 4–5 mm/wk; and individuals are reproductively capable at between 1 and 2 mo of age (Jonathan Fajans, University of Florida, Department of Fisheries & Aquatic Sciences, pers. comm.). From Tampa, currents have dispersed larvae south along the Gulf Coast to Boca Grande outside of Charlotte Harbor (Benson et al. 2001).

In 2002, reports of the green mussel surfaced on the northeast coast of Florida in the St. Augustine area (Dr. Richard Gleeson, Guana Tolomato Matanzas National Estuarine Research Reserve).

Because the mussel has not yet arrived in the Florida Keys, it is unlikely that the occurrence of the green mussel in Georgia resulted from larval dispersal around the peninsula. This may represent an entirely new introduction, however it is more likely to have resulted from boats and equipment being transferred between coasts without adequate cleaning of attached organisms and draining of bilge water. During early 2003, currents carried the mussel as far north as Jacksonville Beach, Florida and fears arose that it would soon appear in Georgia.

The University of Georgia Marine Extension Service (UGA MAREX) in collaboration with the University of North Carolina at Wilmington are currently conducting a Sea-Grant-funded biologic survey of the major shipping ports in the southeastern United States (Jacksonville, Florida; Savannah, Georgia; Charleston, South Carolina; and Wilmington, North Carolina) for invasive species. The Sapelo Island National Estuarine Research Reserve (SINERR) is also investigating invasives in the Sapelo Island area of coastal Georgia as part of a national monitoring program. In anticipation of the green mussels' arrival, UGA MAREX and SINERR prepared an informative flyer, which was distributed to commercial fishermen, and posted it at marinas and public boat ramps throughout coastal Georgia. The species appearance and biology was described, a photo was included, and anyone finding one of these mussels was urged to collect the specimen and file a report.

The first report in Georgia came in early 2003, from biologists in the Department of Natural Resources (DNR), who observed many green mussels inhabiting artificial reef G, approximately 30 miles offshore from Brunswick (Fig. 1). Green mussels were again observed there during the summer months. Later in the fall, we began to receive reports from throughout the coastal area of Georgia between Savannah and Brunswick (Plantation Creek, Mackay River, Fredrica River, Savannah River, Skidaway River, and Tybee Beach; see Fig. 1). Mussels were collected from the surface to approximately 4.5 m in depth. Mussels were found subtidally on old abandoned crab traps, crab trap floats, rope, boat fenders, and also in the lower intertidal zone on beach jetties. With the exception of the jetties, all other reports were single specimens. The largest living specimen recorded was 70 mm in length, 35 mm in height, and 23 mm in width. The average shell length of

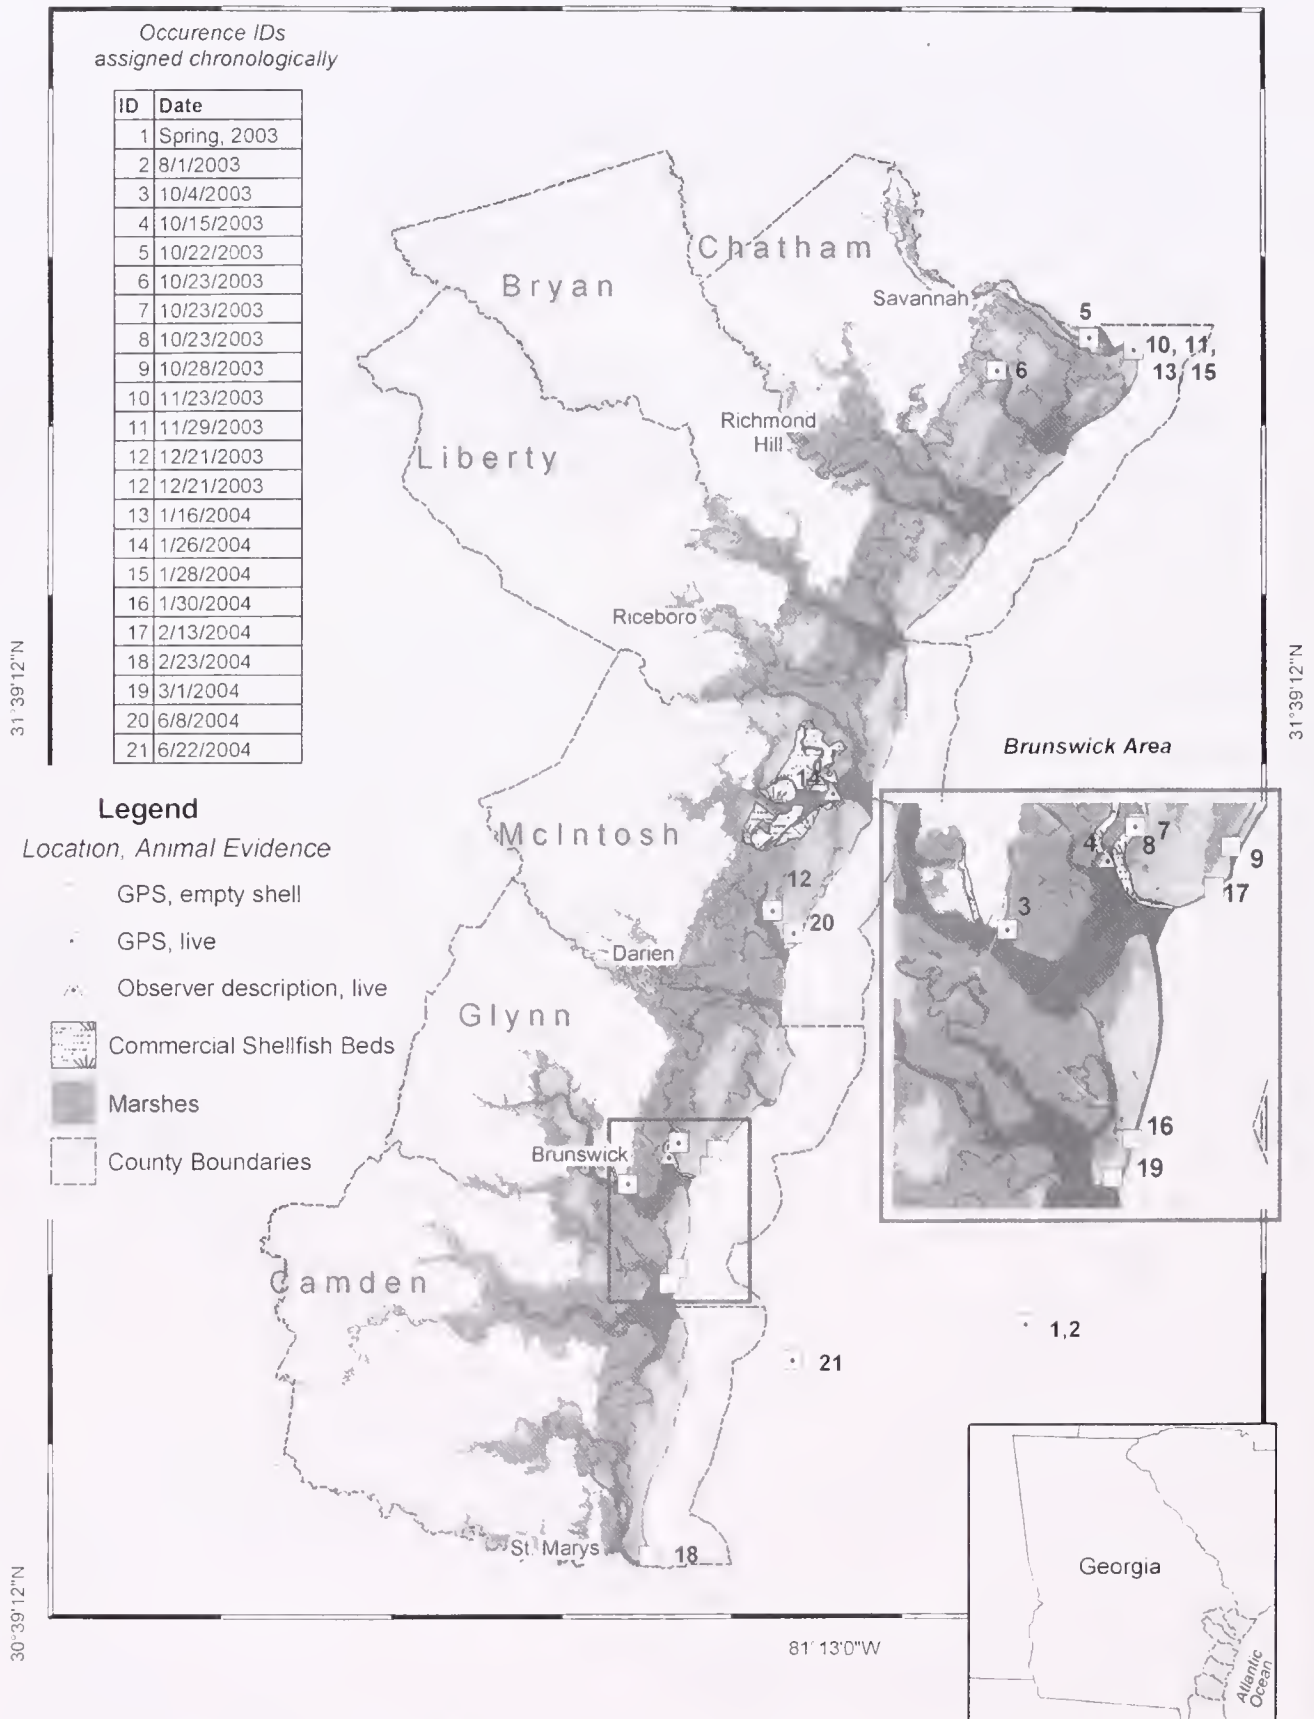

Figure 1. Reported occurrences of the green mussel, *Perna viridis* throughout the coastal counties of Georgia (GA). Observations are numbered chronologically and each specimen is identified as living or dead, and located by GPS or observer descriptions. Because many occurrences were reported from Brunswick, an enlarged insert of this area is also included.

all mussels found during the fall ($N = 18$) was 34.44 mm (± 2.98 S.E.).

During winter 2004, all intertidal individuals on the jetties died. A greater tidal range exists here than in Tampa, and possibly the longer periods of exposure to low air temperatures will limit the mussels' survival in the intertidal zone. This is beneficial to Georgia's oyster reefs, which are primarily intertidal (Harris 1980). Green mussel shells were washed ashore coastwide over the winter (Sea Island, Tybee Island, Jekyll Island, St. Simons Island, and Cumberland Island; see Fig. 1). The largest shell washed ashore measured 95 mm in length.

Only one resident live mussel has been found in inshore waters in 2004; it was pulled from an abandoned crab trap in Sapelo Sound during January (see Fig. 1). It is likely that others have survived the winter in the subtidal zone. On June 8, 2004 a single specimen was found in Dean Creek near Sapelo Island, attached to a floating piece of wood (see Fig. 1). Six live mussels were also collected by the DNR on June 22, 2004 from buoy markings at Georgia Artificial Reef "A", which are 7 nautical miles east of Little Cumberland Island (see Fig. 1). These individuals ranged in shell length from 28.8 to 73.4 mm (mean \pm SE = 50.0 ± 7.9). We may see newly recruited mussels occurring in inshore waters during the warm summer and fall months, because the lower temperature threshold for gametogenesis of 24°C (Lee 1988) is typically attained during the month of May in Georgia.

These observations represent the current most northerly reported occurrence of the species in the United States. None have yet been recorded from South Carolina (David Knott, South Carolina Department of Natural Resources, Southeastern Regional Taxonomic Center, pers. comm.). However, established breeding populations in Georgia in combination with mild winters would make this expansion a likely scenario. In Japan, where the species has also been introduced, populations have managed to survive the severest winters in certain areas due to warm water discharges from several factories (Umemori & Horikoshi 1991).

An interesting side observation of the present survey was the rare documentation of 2 *Mytilus edulis* (L.) individuals in October 2003, one from the Brunswick area and another from Sapelo (identified by Dr. Paula Mikkelsen, American Museum of Natural History). This common bivalve of the northeastern United States region typically does not occur as far south as Georgia.

The zebra mussel, *Dreissena polymorpha* (Pallas 1771), a native of Eastern Europe, is an infamous freshwater ballast invader that occurs in over 40% of America's inland waterways. Close to \$1 billion has been spent on controlling the species in this country over the last 15 years. A marine counterpart to the zebra mussel in the southeastern United States could be the green mussel. Witnessing the economic and environmental problems experienced in the Tampa Bay region on the Gulf Coast of Florida since the introduction of the green mussel there a few years ago, has led to considerable concern in the coastal community of Georgia. UGA and SINERR have recently initiated a specific green mussel monitoring survey in which devices that offer a variety of settling surfaces (Hester Dendy fouling plates, rope, artificial seaweed, and pvc sheets) have been deployed subtidally in various salinities throughout coastal Georgia. Quarterly sampling will provide an assessment of the distribution and abundance of the species here in Georgia and will provide information about its ecological and environmental tolerances for eventual prediction of the geographic and ecological impacts that could occur due to this organism.

ACKNOWLEDGMENTS

The University of Georgia Marine Extension Service, Sapelo Island National Estuarine Research Reserve and NOAA's National Sea Grant Aquatic Nuisance Species Program provided funding for this work. Thanks to Dr. Amy Benson (United States Geological Survey), Mr. Jonathan Fajans (University of Florida), Dr. Harry Lee (Jacksonville Shell Club), and Dr. Richard Gleeson (GTMNERR) for providing information on the Florida green mussel invasion. Thanks to Dr. Marc Frisher (Skidaway Institute of Oceanography) and Dr. Paula Mikkelsen (American Museum of Natural History) for assisting with the positive identification of specimens. Finally, thanks to all those who have participated in these surveys: Mr. Dwight Vernado, Mr. Henry Ansley, Mr. Dominic Guadagnoli, Mr. Brooks Good, Mr. Gabe Gaddis (Georgia Department of Natural Resources), Ms. Ellie Covington, Ms. Marcy Mitchell, Ms. Mary Sweeney-Reeves, Mr. James Nichols, and Dr. Mare Timmons (University of Georgia Marine Extension Service), Dr. Dale Bishop (University of Georgia School of Marine Programs), the Jekyll and Tybee Island 4-H Centers, the Tybee Island Marine Science Center, and members of the public.

EVALUATION OF THE NEUTRAL RED RETENTION ASSAY AS A STRESS RESPONSE INDICATOR IN CULTIVATED MUSSELS (*MYTILUS* SPP.) IN RELATION TO SEASONAL AND ENVIRONMENTAL CONDITIONS

JOANNE M. HARDING,¹ CYR COUTURIER,¹ G. JAY PARSONS^{1*} AND NEIL W. ROSS²

¹Fisheries and Marine Institute, Memorial University of Newfoundland, P.O. Box 4920, St. John's, Newfoundland and Labrador, Canada A1C 5R3; ²National Research Council, Institute for Marine Biosciences, 1411 Oxford Street, Halifax, Nova Scotia, Canada B3H 3Z1

ABSTRACT The neutral red assay (NRA) was evaluated as an indicator of stress response in mussels that were held under various culture situations. The NRA measures retention time of neutral red dye in the hemocyte organelle, the lysosome, which can be correlated to the condition of a mussel under stressful circumstances. Shelf life and standard meat yield also provide an indication of mussel condition. The objectives of this study are to compare and evaluate mussel stress response in relation to: (1) seasonal and environmental changes and (2) postharvest handling. Neutral red retention (NRR) levels and shelf life were reduced in late summer mussels (postspawning) compared with early summer mussels (prespawning), and increased in autumn/early winter mussels, indicating a seasonal pattern of stress response associated with reproduction. Harvested mussels exhibited a decrease in NRR during extended air exposure, especially when held at air temperatures above and below air temperatures comparable to ambient water temperatures. The results demonstrated that NRA was a useful, sensitive index of physiological stress response in mussels subjected to various culture practices and conditions. The implication of this work for mussel growers is that reduced air exposure following harvest and reduced handling during certain seasons will result in less stressed mussels and hence a better quality product.

KEY WORDS: mussel culture, neutral red assay, stress response

INTRODUCTION

The blue mussel (*Mytilus* spp.) culture industry in Canada has been on a rapid increase since the mid 1980s. In Newfoundland, with the onset of various programs such as the spatfall monitoring program, environmental and biological monitoring program, and product quality programs, the overall quality and quantity of blue mussels continues to improve (Clemens et al. 1999, Macneill et al. 1999). Because the market demand continues to rise for the Atlantic Canada mussel industry, a better understanding of how various production parameters (i.e., environmental and handling conditions) affect mussels need to be examined and evaluated to determine when or how conditions may become detrimental and reduce the quality of the product.

During the process of culturing mussels, there are several seasonal and short-term environmental factors that the mussels are exposed to while in the growout phase, including changes in water temperature, salinity, and food availability. Stress can be defined as any environmental stimulus that disturbs normal function in an organism, and that any reaction in the organism to this stress is the stress response (Bayne 1985). Under some circumstances conditions during the culture of mussels can have a negative impact on the mussels and may induce a stress response. Stress response in animals is dynamic, and results in the alteration of functional properties that can be quantified with the environmental stimuli (Bayne et al. 1976, Koehn & Bayne 1989). To date, stress response by mussel growers has generally been observed at the whole animal level with a reduction in performance such as growth, feeding, condition, and/or quality.

During the growth period of cultured mussels in Atlantic Canada they are completely and continuously submerged in water, and are subject to seasonal and environmental conditions associated with the reproductive cycle, hydrographic events, food avail-

ability, and fluctuating water temperatures. High mortalities have been associated with reproduction, genetics, starvation, and water temperatures, all of which may be influenced by oceanic events (i.e., tidal or wave action, currents) (Freeman & Dickie 1979, Worrall & Widdows 1984, Carver & Mallet 1991, Sephton et al. 1993, Myrand & Gaudreault 1995). As well, during harvesting, mussels can be exposed to a number of environmental factors including abrupt exposure to extreme air or water temperatures, sunlight, rain, and wind, any of which can pose stress on mussels and induce some form of stress response (Warwick 1984, Widdows & Shick 1985, Eertman et al. 1993).

The need to develop earlier and more rapid indicators of stress responses in mussels is ongoing and previous studies have shown changes in physiological characteristics under a number of conditions in feral blue mussels (Bayne 1973, Thompson et al. 1978, Moore et al. 1979, Lowe et al. 1995a, b, Tremblay et al. 1998a, b). Past research on various bivalve species subjected to a number of stressors has shown that the site of earliest detectable stress response is in the lysosome, an organelle of the hemocytes (Moore et al. 1979, Moore 1980, Bayne et al. 1981a, b, Lowe et al. 1995a, b). The NRA can be used to measure alterations in lysosomal stability induced by various stress factors. In their stable form (no stress response), lysosomes will accumulate and retain the neutral red dye for an extended period of time. However, once destabilized (stress response) following a stressor, the lysosomes will coalesce to form larger lysosomal structures and the neutral red dye will leak into the cytosol of the cell through damaged membranes (Moore 1980, Lowe et al. 1995a). The rate of lysosomal changes following the addition of the neutral red dye is indicative of the stress response and can be directly related to the degree of stress being imposed on the mussels.

The objectives of this study are to evaluate the NRA as a stress response indicator in cultivated mussels at the subcellular level (lysosomes), in relation to seasonal and environmental changes and to postharvest handling.

MATERIALS AND METHODS

Study Site and Animals

This study was carried out using market size mussels (i.e., >50 mm shell length), which were grown and harvested at Charles Arm, Notre Dame Bay, Newfoundland (49.34 N, 55.28 W) from the period of June 2001 to June 2002. Mussels from this site are >90% *Mytilus edulis* and <10% *Mytilus trossulus* or hybrids (Penney et al. 2001). Charles Arm is a small semiencloded site of an axial length ~3.1 km and connected to the sea by a narrow channel <100 m in width (Penney et al. 2001). Mussels were randomly obtained from mussel socks located on longlines in the middle of the site and shipped in coolers with ice packs to the Marine Institute (St. John's, NL) where they were maintained in flow through raceway systems of seawater at ambient temperature and salinity for at least 2 days prior to experimental use (Harding et al. 2004b).

Experimental Design and Set-up

To assess the seasonal pattern of naturally (physical and biological) induced stress response, mussels were sampled monthly from the culture site from June 2001 to June 2002, with the exception of April 2002 due to ice conditions at the site. Seasonal measurements took into account that there was a natural algae bloom in the late summer to early autumn and in the spring of the year, the normal spawning period in June (assessed by a decline in condition index), and that the water temperature was in the range of 2°C (winter) to 15°C (summer). Measurements of food supply (Chlorophyll-a [Chl-a]), condition index (meat yield), and temperature at the Charles Arm site were monitored on a monthly basis up until November 2001 (see Fig. 2 later) (Nichols et al. 2002). The NRA ($n = 12$ for each monthly sampling), shelf life (3 replicates of 50 mussels for each monthly sampling), and condition index (standard meat yield) were measured against seasonal changes.

To assess the effects of air temperature and extended air exposure on the mussels' subcellular stress response, animals were sampled following harvesting, and following a 2-day recovery in the laboratory (ambient seawater, temperature, and salinity) at 4 times over a year; early summer (June 2001, pre-spawn), late summer (August 2001, post-spawn), early winter (January 2002, recovered), and spring (May 2002, overwinter / early pre-spawn). In one experiment, unprocessed mussels were exposed to air temperatures below, equal to, or above ambient water temperatures, at various times of year. Thermal differentials were in the range of 5°C to 10°C (Table 1). In a second experiment, unprocessed mussels were exposed to air temperatures below, equal to, or above the ambient water temperature of 5°C as observed for that time of the year, with differentials in air temperature of 5°C to 20°C. Mussels were exposed to each temperature for an 8-h period with samples ($n = 12$ mussels) for the NRA being taken at hour 0 as a control, and at hours 4 and 8 for each temperature exposure.

Sampling Procedures

The NRA was performed using the method described by Lowe et al. (1995a) with minor modifications; poly-L-lysine and neutral red stock solutions were increased from 10 µL to 20 µL to enhance cell adhesion to microscope slides and dye intensity in the cells, respectively. Briefly, 0.3 mL of hemolymph was drawn from the posterior adductor muscle into an equal amount of physiological

TABLE 1.

Air temperature exposures (below, equal to, and above ambient water temperature) during the various seasons of early summer (June 2001), summer (August 2001), early winter (January 2002), and spring (May 2002).

Season	Below Ambient Water Temperature (°C)	Ambient Water Temperature (°C)	Above Ambient Water Temperature (°C)
Early summer	2	7	17
Summer	6	16	21
Early winter	-3	2	12
Spring	0	5	15

saline using a 21-gauge needle, with the mixture placed in a siliconized Eppendorf tube and gently inverted. A 40-µL sample of the hemolymph/saline mixture was then placed onto a microscope slide that had been treated with poly-L-lysine. The cells were then left for 15 min to adhere to the slide. A neutral red working solution was prepared from 20 µL of neutral red stock solution and 5 mL of physiological saline, and 40 µL was added to the cell layer and incubated for 15 min in a humidity chamber. After 15 min of incubation, a cover slip was added to the slide and the cells were examined under low light intensity using a compound microscope at ×400 magnification. Cells were examined every 15 min for the first 60 min, then at 90, 120, and 180 min.

For each examination, 25 hemocytes from each mussel sample were examined and given a rating based on 1 of the 4 following characteristics: No stress response = characterized by appearance of tiny pink dots, which are intact lysosomes containing neutral red dye; moderately low stress response = increase in the size of lysosomes due to lysosomal membrane fusion; moderately high stress response = lysosomes appear larger and more faint in color due to fusion of lysosomal membranes and leakage of neutral red dye into the cytosol; high stress response = cytosol is completely tinged pink due to leakage of neutral red dye out of the lysosomes, and only remnants of the lysosomal membranes may be still visible. When higher than 50% of the 25 cells exhibiting high stress response at a particular time point, then the assay was stopped for that mussel and the previous examination time period recorded as the score for NRR.

Shelf life was defined as the time when 5% of mussels in a sample were dead or moribund in a lot. For each monthly sample, 3 replicates of 50 mussels were assessed. Mussels were placed in chilled dry storage of 2°C to 4°C at high humidity, the accepted industry method, each month. Shelf life trials were terminated at day 20, by which time mussels had a strong odor, which would make them unmarketable by industry standards, from initiation of the experiment regardless whether 5% mortality had been reached. Mussel mortality or morbidity (shells fail to remain closed) was assessed daily.

Standard meat yield (CI = condition index) was determined by the following calculation based on 1 kg of live mussels, which were steamed for 10 min (Ibarra et al. 2000):

$$CI = \frac{\text{cooked meat weight}}{(\text{cooked meat weight} + \text{shell weight})} \times 100$$

Data analysis

Data were analyzed using the SPSS (version 10) statistical software. The means (\pm SE), ANOVA, and *post hoc* tests (Tukey's b) were calculated. The level of significance was set $\alpha = 0.05$.

RESULTS

Seasonal Variation

Monthly sampling of mussels showed a seasonal pattern in stress response (Fig. 1A). NRR, a measure of subcellular (lysosome) stress response, showed a significant difference among the months (one-way ANOVA; $F_{(11,130)} = 21.327$, $P < 0.001$), with significant decreases in NRR following spawning events in June 2001, September 2001, and June 2002 (Tukey's b, $P < 0.05$) followed by gradual increases in NRR in the months following spawning.

The average shelf life of mussels examined during each of the monthly samplings showed that there was a significant difference among the months (one-way ANOVA; $F_{(11,24)} = 15.675$, $P < 0.001$) (see Fig. 1B). The average time mussels can survive before they reach 5% mortality was reduced during certain times of the

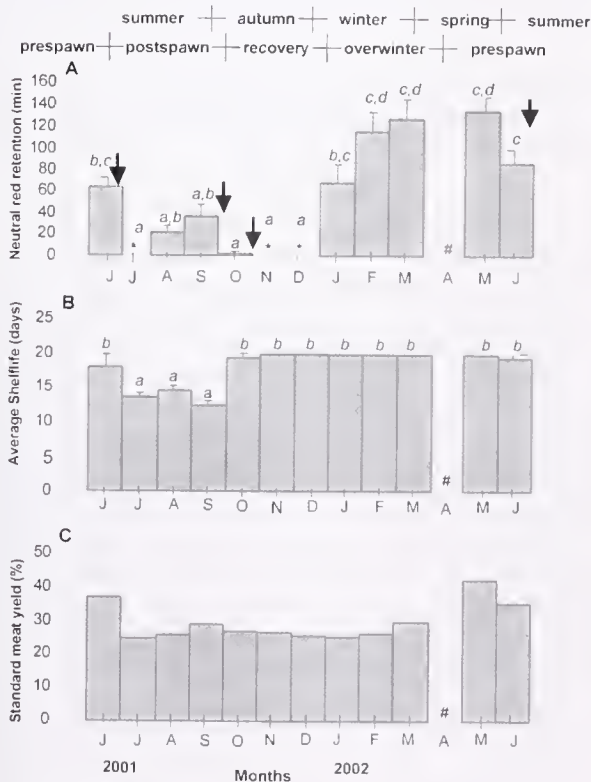

Figure 1. Seasonal variation of neutral red retention, average shelf life, and standard meat yield of *Mytilus* spp. Common letters denote no significant difference among treatments (Tukey's b, $P > 0.05$). (A) Neutral red retention in lysosomes during summer, autumn, winter, and spring conditions. Bars represent the mean \pm SE, $n = 12$ mussels for each month. ANOVA: $P < 0.001$. (* indicates mean = 0); (B) Shelf life in average number of days for 5% mortality to be reached. Each bar represents the mean \pm S.E., $n = 3$ replicates of 50 mussels for each month. ANOVA: $P < 0.001$; (C) Condition index as by standard meat yields. Arrows indicate spawning events. Note: no samples were collected for the month of April (#).

year, especially following the major spawning period in June (see Fig. 1A, B).

The condition of the mussels, as determined by a standard meat yield, showed meat yields decreased following spawning events and gradually increased in months following spawning (see Fig. 1C). Comparison of NRR, shelf life, meat yield and parameters of food availability (Chl-a), temperature, and salinity indicate that NRR and shelf life are influenced by various combinations of these parameters at various times of the year (Fig. 2). NRR was shown to be most affected by the reproductive cycle (determined using standard meat yield) with a significant correlation, $r = 0.87$, and shelf life being influenced inversely by water temperature with a correlation of $r = -0.74$ (Table 2). Regression analysis on the correlation between NRR and meat yield showed significance with $R^2 = 0.75$ ($P = 0.025$), however between temperature and shelf life significance was lower with $R^2 = 0.54$ ($P = 0.9$) (Fig. 3 A,B).

Air Exposures

Experiments examining the rapid, short term exposure of mussels to various air temperatures showed that the NRR response was affected by variation in air temperature, duration of the exposure during harvesting (< 8 h), and seasonal factors (Fig. 4). There was a significant interaction between the seasons and the air temperatures (ANOVA; $F_{(6,371)} = 5.786$, $P < 0.001$), between the seasons and the hours of sampling (ANOVA; $F_{(6,371)} = 6.164$, $P < 0.001$), and between the air temperatures and the hours of sampling (ANOVA; $F_{(4,371)} = 6.084$, $P < 0.001$).

A seasonal pattern of mussel stress response was apparent as NRR (observing time zero for each season) was reduced in months surrounding the spawning period (see Fig. 4). Mussels had low NRR in the postspawning period but this was significantly higher in all other sampling periods. Seasonally, the NRR scores showed that there was no significant difference between mussels in June 2001 (prespawning) and January 2002 (recovered), but that there was a significant difference in mussels in August 2001 (postspawning) and in mussels in May 2002 (overwintered) than all the other seasons respectively (Tukey's b, $P < 0.05$).

In general, results showed that NRR scores of normally submerged mussels subjected to rapid, short term air exposure and held at an air temperature equal to ambient water temperature were significantly higher than any other air exposure temperature. The

air temperatures used in this experiment are given in Table 1. Furthermore, NRR scores of mussels held at air temperatures that were below the ambient water temperature were significantly higher than NRR scores of mussels held at an air temperature that was higher than the ambient water temperature, with the exception of when air below the ambient water temperature was at subzero temperature (Tukey's b , $P < 0.05$). Mussels held at air temperatures that were equal to ambient water temperatures had the highest NRR scores (and less stress) regardless of season or period of time of exposure compared with NRR scores of mussels held at air temperatures either below or above the ambient water temperature (see Figs. 4A, B, and D).

In addition, this experiment showed that short term extended air exposure on mussels reduced NRR in all seasons and temperatures, as NRR scores were significantly different among the hours (ANOVA: $F_{(2,371)} = 136.857$, $P < 0.001$, Tukey's b , $P < 0.05$) (see Fig. 4D). Further examination of air temperature exposure

Figure 3. Seasonal parameters found to be significantly correlated for the period of June 2001 to November 2001 inclusive. (A) Neutral red retention and standard meat yield; (B) Temperature and shelf life.

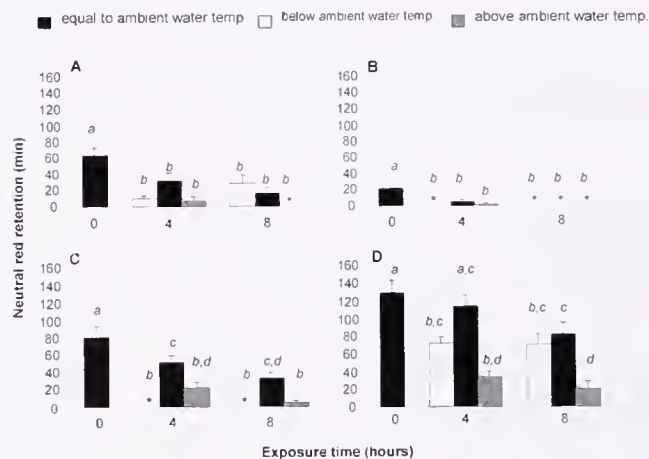

Figure 4. Neutral red retention in lysosomes of *Mytilus* spp. exposed to various air temperatures. Bars represent the mean + SE, $n = 12$ mussels. ANOVA: $P < 0.001$. (* denotes mean = 0). Common letters denote no significant difference among treatments within each season (Tukey's b , $P > 0.05$). (A) Early summer mussels (June 2001, prespawed); (B) Summer mussels (August 2001, postspawed); (C) Early winter mussels (January 2002, recovered); (D) Spring mussels (May 2002, overwintered). See Table 1 for temperature treatments.

showed that NRR declined more rapidly when mussels were exposed to greater differentials in air temperatures in relation to the ambient water temperature of 5°C (Fig. 5).

DISCUSSION

Seasonal and Monthly Variations

The objective of this study is to examine effects of seasonal influences on cultured mussels using and evaluating the NRA as a stress response indicator. The significant difference in NRR among the months and seasons indicates that seasonally related factors were influencing natural and normally induced levels of stress response in mussels. This was an expected occurrence because previous studies have shown that there are differences in a number of physiological factors among the seasons, especially between the warmer and colder months (i.e., summer and winter) (Bayne & Thompson 1970, Moore 1976, Hofmann & Somero 1995, Chapple et al. 1998). Metabolic rate has been shown to differ from summer and autumn to the winter, lysosomal responses have been reported to differ from winter to the summer, and protein levels vary seasonally in feral bivalves (Bayne & Thompson 1970, Moore 1976,

Figure 5. Neutral red retention in lysosomes of *Mytilus* spp. exposed to various air temperatures during spring (May 2002). Bars represent the mean + SE, $n = 12$ mussels. ANOVA: $P < 0.05$. Common letters denote no significant difference among treatments (Tukey's b , $P > 0.05$). Ambient water temperature during this period was 5°C.

Hofmann & Somero 1995, Chapple et al. 1998). Conditions that change with the seasons, including reproductive patterns, water temperatures, and food availability, can lead to major alterations in physiologic mechanisms because the animal strives to maintain homeostasis (Bayne & Thompson 1970, Moore 1976, Hofmann & Somero 1995, Chapple et al. 1998).

The seasonal pattern of natural stress response levels in cultured mussels was shown to be closely related to the reproductive cycle as determined by the standard meat yield (condition index). Spawning events were a factor each time NRR decreased. NRR decreases were observed to significantly correlate with a decrease in condition index. Previous research has shown changes in physiological activities occur during the reproductive cycle in feral mussels including high lysosomal destabilization, higher metabolic demands, lower survival, reallocation of energy, lower oxygen consumption, fluctuations in plasma components, and changes in body glycogen and byssal thread production (Bayne & Thompson 1970, Bayne 1973, Thompson et al. 1978, Worrall & Widdows 1984, Young 1985, Eertman et al. 1993, Myrand & Gaudreault 1995, Tremblay et al. 1998b). The present findings on cultivated mussels support these earlier studies on wild mussel populations.

Naturally induced stress response levels continually decreased throughout the winter months as NRR increased, and only began to decline again in late spring/early summer (June 2002), which was comparable to stress response levels in the previous year (June 2001). Previous studies that examined the reproductive cycle in wild mussels have shown that gametogenesis occurs very slowly during the winter and that its progression is rapid in the spring and early summer, followed by spawning in July (Thompson 1984), thus suggesting a link between stress responses and the breeding cycle.

To further understand seasonal variation of natural stress response levels in mussels, shelf life was also examined as an indicator of stress response at the whole animal level. The shelf life varied little throughout the year with the exception of July 2001 through to September 2001 following the major spawning period. Furthermore, the condition index of mussels was highest prior to spawning and lowest following spawning. These findings support the results of previous studies that showed mussels are in poor condition and have low meat yields following spawning, and they undergo a number of physiological changes during this time that can impede survival ability (Bayne & Thompson 1970, Bayne 1973, Dare & Edwards 1975, Slabyj & Hinkle 1976, Warwick 1984).

Seasonal variations as illustrated by the NRA, shelf life and meat yields can be affected not only by reproduction, but also by seasonal changes in temperature and/or food availability. Seasonal trends in water temperature and food availability (leading to nutritive stress) have been shown to affect byssal production, lysosomal stability, disease (bacterial challenges), and metabolic activity in wild mussels and other bivalve species (Bayne 1973, Young 1985, Hauton et al. 1998, Hauton et al. 2001).

In October and November following spawning, NRR and condition index were significantly lowered, however shelf life continued to increase. Although the NRA measured a high stress response in the months of October and November, rapidly declining water temperatures going into these months, and increased food availability from the autumn phytoplankton bloom prior to these months at the sampling site, Charles Arm, enhanced the survival ability of mussels by reducing the impact of high stress response levels at the subcellular level up to the whole animal level. This study showed that water temperature and shelf life were strongly

linked. Previous studies have shown that mussels are unable to cope with seasonally elevated water temperatures, particularly postspawn, thus a decrease in water temperature would be a benefit to the survivability of the mussels (Sephton et al. 1993, Myrand & Gaudreault 1995). Koehn and Bayne (1989) indicated that with an abundance of energy reserves available, physiological performance of individuals may not be significantly affected by differences in their metabolic efficiency. As suggested by Tremblay et al. (1998), individuals with lower maintenance requirements (related to low water temperature and increased food) would have better survival. In Newfoundland, total particulate matter is highest in summer in more open areas, but is higher in the autumn and spring in small semienclined inlets such as Charles Arm (Thompson 1984, Penney et al. 2001), thus suggesting that food availability was a factor in enhanced, sustained shelf life in the fall, as were seasonally lower water temperatures.

In general, the combination of thermal, nutritive, and reproductive stress influenced the outcome of stress response as assessed by NRA, shelf life and meat yield of mussel. Experiments that evaluated the effects of air temperatures as found during harvesting on barge decks on stress response in mussels corroborated the impacts of these seasonal influences.

By examining stress response using the NRA, in conjunction with the assessment of shelf life and condition index, late autumn (December) through to the spring (May) of the year is the time period when mussels are in the best physiological condition and are least stressed in this subarctic farming site.

Air Exposures

The effects of ambient air temperatures, especially over extended exposure periods, have been shown to be detrimental to mussels (Moore et al. 1979, Widdows & Shick 1985). Understanding the influence of sudden short term air exposure on continuously submerged mussels is important during harvesting on barge decks so as to minimize the impact it may have on the quality of the mussel product. During harvesting mussels are exposed to and maintained in air of various temperatures for relatively short periods of time (<8 h), and they enter an anoxic state bringing about changes in physiological parameters (Moore et al. 1979, Widdows & Shick 1985). These changes are an immediate response to a new environment and in the case of harvesting are a reaction to a short term event that does not allow the mussels time to adapt physiological processes that would later be apparent if time in this condition was extended.

As expected, the results of our experiments showed that exposure to air temperatures equivalent to seasonal ambient water temperatures were least detrimental to mussels, as assessed by the NRA. In general, during summer months, subcellular stress response, as measured by NRR, was high at any exposure temperature and can be attributed to seasonal influences of reproduction. Overall, air temperatures within 5°C of ambient seawater temperatures had little additional effect on mussel stress response, but those mussels exposed to a greater thermal change had a proportionally greater response. Air temperatures that exceeded ambient water temperature by 15°C induced the highest stress response in mussels. Air temperatures vary throughout the year and may harm mussels if they are exposed for extended periods (Widdows & Shick 1985). Moore et al. (1979) demonstrated that in mussels, *Mytilus edulis*, and cockles, *Cerastoderma edule*, an exposure to an increase in air temperature of 10°C induced no change in

lysosomal activity, but did with a 20°C increase, which is in accordance with the present findings. Our study also found that mussels were under high stress during air exposure at subzero temperatures. Past studies have shown that there is a high incidence of mortality in mussels harvested during subzero temperature, and that although *Mytilus edulis* can tolerate freezing up to about -10°C, tissues become injured when 64% of the cellular water is removed to form ice (Williams 1970, Slabyj & Hinkle 1976, Slabyj 1980). In this work, exposure of winter harvested mussels to -3°C air temperature (5°C below ambient water temperature), induced a significant reduction in NRR compared with air temperature equivalent to the ambient water temperature of 2°C.

Experiments revealed that extended exposure to air, no matter what the temperature, increased stress response in mussels during every sampling season. Previous studies support this finding, because aerial exposure has been shown to cause physiological changes, such as altered lysosomal stability in wild *Mytilus edulis* and the clam, *Mya arenaria*, ammonia accumulation in plasma, and increases in the number of hemocytes in mussels (Thompson et al. 1978, Eertman et al. 1993, Tremblay & Pellerin-Massicotte 1997).

Examinations of stress response associated with air exposure suggest that harvesting on barge decks should occur when air temperatures are close to being equivalent to ambient water temperatures, and prolonged period of air exposure should be avoided when air temperatures are below 0°C. If air temperatures exceed a 5°C differential from ambient water temperatures, mussels should be covered to avoid undue stress responses and subsequent reduction in shelf life that may be induced by heating in the sun in summer or freezing in the winter. As well, extended holding of mussels on harvesting decks should be minimized to less than 4 h in duration during any season, unless alternative approaches, such as icing the mussels, can be arranged. The present work suggests that by manipulating or altering standard culture practices we may improve mussel quality and production, and in the end profits for growers.

Shelf Life and Industry Practices

The findings of air exposure on barge decks do not address shelf life issues. Shelf life is a long process extending days as opposed to just hours and provides time for mussels to adapt to anoxic conditions. Exposure to air during harvesting induces initial

physiological changes with the onset of anoxia in mussels and to the air temperatures in which mussels are being harvested, and are not reflective of the survivability of mussels during extended, storage conditions. Concurrent studies with this work examined the effect of various storage conditions, including storage in air, and duration of storage on stress response (i.e., NRA) and shelf life of mussels during the same sampling periods (Harding et al. 2004a).

The NRA can be used successfully to examine stress response levels in lysosomes of cultured mussels, and to determine if various conditions to which cultured mussels are exposed, such as air temperatures, will induce a stress response at the subcellular level in the lysosomes. The NRA can provide information about culture conditions and their effects on mussels, and there are several questions remaining to be answered. For example, can the NRA be used to predict how non market-sized mussels respond to certain conditions while in the water, or during times of grading and socking. As well, the question of genetics and stress response need to be addressed. Different species may have different adaptive abilities and thresholds of tolerance to a variety of conditions. Studies are needed to quantify stress response in mussels of different genetic makeup.

The question of how physiological parameters correlate with the lysosomal stress response changes needs to be examined. The lysosome has been identified as the site of earliest "detectable" change to the state of the mussel, and presuming that the role of lysosomes is largely immunological in hemocytes, it is conceivable that the stress response, as reflected by changes in protein concentrations, O₂ consumption, ammonia levels, and hemocyte activity may be triggered by lysosomal changes. Hence, there is a need to examine the integration of all these processes. Understanding these interactions may lead to development of earlier indicators that the animal has been exposed to stressful conditions and allow for earlier manipulations of conditions to avoid expression of the stress response at the whole animal level.

SELECTION RESPONSE FOR GROWTH RATE (SHELL HEIGHT AND LIVE WEIGHT) IN THE CHILEAN BLUE MUSSEL (*MYTILUS CHILENSIS* HUPE 1854)

JORGE E. TORO,* ANGÉLICA C. ALCAPÁN, JOHANA A. OJEDA AND ANA M. VERGARA

Instituto de Biología Marina, Universidad Austral de Chile, Casilla 567, Valdivia, Chile.

ABSTRACT The parental stock was taken from the 1999 natural spatfall of *Mytilus chilensis* collected in the Yaldad Bay of southern Chile. From the 22-mo-old cohort 5,688 mussels were monitored for live weight and shell length. Selection was carried out by applying a selection intensity of 1.755 for the trait “live weight”. Five selected lines and five lines of an unselected control group were conditioned in seven 150-L tanks. Juveniles from the 3 selected and 2 control lines were individually tagged and transferred to three geographically distant mussel farms in southern Chile. Live weight and shell length were monitored after 10, 14, 18, and 22 months of age in all experimental mussels. The ANOVA results showed a significant difference, in both traits, between the selected and control groups at every age and location. Realized heritabilities for the trait “live weight” ranged between $h^2 = 0.35$ and $h^2 = 0.54$, whereas those for the trait “shell height” ranged between $h^2 = 0.32$ and $h^2 = 0.49$. Genotype-environment interactions were not apparent for either trait, indicating that similar selection pressures result in similar phenotypic changes for these traits across environments. These results suggest that mass selection for the improvement of the traits live weight and shell height would be effective in the Chilean mussel broodstocks.

KEY WORDS: mussel, *Mytilus chilensis*, selection response, growth, Chile

INTRODUCTION

Mussel aquaculture has enormous potential in southern Chile mainly because the numerous sheltered bays and estuaries along its coastline are free from industrial pollution. Fertilizers and pesticides are rarely applied in local agriculture, and domestic pollution, because of the low human population densities in southern coastal areas. (Winter et al. 1984, Toro & Chaparro 1990).

The Chilean blue mussel *Mytilus chilensis* (Hupe 1854) is an economically important bivalve in southern Chile. Its culture began in 1943 in the area of Quellón located southeast of Chiloé Island (Navarro & Gutierrez 1990, Aiken 1993) and the aquaculture production of this species increased from 3,864 t in 1993 to 41,406 t in 2001 (SERNAPESCA 2002). These values indicate an increase of 971.5 % (37,542 t) for mussel aquaculture between 1993 and 2001. Greater production space (hectares) under cultivation rather than higher outputs per unit area accounts for most of this increased production (Sanchez 2002). However, social, ecological, and economical pressures will eventually promote a greater efficiency of these aquaculture production systems. There are various means to achieve this goal: improved husbandry, nutrition and disease control, and improvement by genetic means. The potential for improving performance by genetic means is unquestionably substantial. There are several reports in the literature addressing the importance and potential of genetics in aquaculture (Moav 1976, Newkirk 1983, Gjerde 1986, Guíñez 1988, Toro & Newkirk 1990, Gjedrem 1999, Koment 2002, Beaumont & Hoare 2003). Increasing production efficiency, reducing generation time, and/or improving survival rate will reduce the negative effects of short growing seasons in high latitudes (Newkirk 1980).

Growth rate has implications for the fitness of individuals and also is considered the most economically important trait to be improved in a selection program (Beaumont & Hoare 2003). Traits of economic importance are usually determined by a large number of genes each having a small contribution and under considerable environmental influence (Newkirk 1980, Lande 1982). Thus, these

traits are best studied through the quantitative genetic theory that reduces the most important features of complex genetic systems to a few variables that can be estimated from phenotypic measurements (Falconer 1989, Lande 1982).

Due to the high market demand for this species, the culture of *M. chilensis* in Chile has been increasing rapidly in the past years (Winter et al. 1984, Navarro & Gutierrez 1990, SERNAPESCA 2002, Sanchez 2002), and because of this mussel aquaculture development, estimates of genetic variation (i.e., heritability) and response to selection pressure are not only important from the ecological point of view but also for practical management purposes (Mallet et al. 1987, Koment 2002). The type of selection scheme that is appropriate depends upon the relative magnitude of the variation of that trait, due to differences in genotype and in environmental factors (Falconer 1989). These mussels are marketable at a shell length of about 55 mm, which is attained after 14 to 16 mo of growth in suspended culture (Winter et al. 1984, Kíno & Valencia 1990). Therefore, a reduction in the time required to attain commercial size (12 mo) could be an important benefit in the culture of this mussel.

Very little has been published on the population genetics of *M. chilensis* and there are no reports on genetic improvement of the Chilean blue mussel. Control of the complete life cycle, which is required for any type of direct genetic improvement (Hershberger et al. 1984), has been accomplished only recently (Toro et al. 2004).

A high intrapopulation variation in the growth rate of *M. chilensis* has been reported in the literature (Winter et al. 1984, Navarro & Gutierrez 1990); however, only a few reports exist on genetic parameters (Toro & Paredes 1996) or genetic manipulation (Toro & Sastre 1995) in *M. chilensis*. A review of the literature shows that heritability estimates in blue mussels have been mainly based on half and/or full-sib correlation (Stromgren & Nielsen 1989, Toro et al. 2004), however, the most appropriate way in a commercial context to determine the heritability of a trait is to carry out selection trials and measure the response to selection for the trait (Beaumont & Hoare 2003). To ensure similar rearing conditions for the selected populations, a control group should also be spawned and their offspring reared in identical environments.

A high heritability value for a particular trait indicates that a

large proportion of the trait is associated with additive gene action, and that genetic progress can therefore be achieved through mass selection (Newkirk et al. 1977). In this study, we consider that h^2 estimates using realized heritability analysis to obtain a more accurate estimation of its values among different rearing locations. To date, there have been no reports on growth and survival of hatchery produced seed of *M. chilensis*. This study represents the first attempt to produce large numbers of juveniles and adults under laboratory conditions and corresponds to a portion of a large-scale breeding program to improve the growth rate of the Chilean mussel *Mytilus chilensis*.

MATERIAL AND METHODS

Adult mussels from a 1999 naturally settled cohort (*Mytilus chilensis* Hupe 1854) were collected from a mussel farm located in Yaldad Bay, Chiloé Island (43°08'S; 73°44'W), southern Chile during October 2001 (prior to the spawning season). At 22 mo of age, a frequency distribution for the trait "live weight" from a random sample ($N = 5,688$) of the cohort of mussels was carried out. The trait presented a normal distribution ($P > 0.05$, Kolmorov Smirnov test, $P > 0.05$). A selection intensity of 1.755 was applied, corresponding to the largest 10% of the trait distribution. A similar number of average-size animals were segregated as control-line parents (Table 1).

Spawning was conducted over a 2-d period. The mussels were kept out of water for about 4–5 h before attempting spawning by thermal shock. They were rinsed in clean seawater and the three selected lines ($N = 200$ each) and 2 control lines ($N = 200$ each) were placed in ten 150-L tanks with filtered (1- μ m) and UV-treated sea water (FSW) at 18°C. They were then continuously monitored until they spawned at which time they were removed. The day after the spawning the water of each tank was filtered through a 45- μ m mesh. The embryos collected from each family were placed into a 200-L fiberglass tank containing 1- μ m filtered and UV-treated fresh seawater (FSW) at $16 \pm 1^\circ\text{C}$, and a density of 100 individuals per mL.

After 48 h the density was adjusted to 5 larvae per mL. A high cell concentration (100,000 cells/mL) of the microalgae *Isochrysis galbana* (Parke 1949) and *Chaetoceros gracilis* (Schuett) were used as food (Toro & Paredes 1996). Every day the water in each tank was passed through a 45- μ m "nitex" screen to retain the larvae. Each beaker was rinsed with fresh water followed by seawater. The larvae were then resuspended in FSW and algal food was added daily at the desired cell concentration.

TABLE 1.

Mytilus chilensis. Basic statistics for the traits "live weight" (g) and "shell height" (mm) for the 5,688 individuals from the 22 months old cohort used as a base population in the selection program.

N	Population 5688	Control 400	Selected 600
Live weight			
Mean (g)	18.47	18.42	26.50
Standard Deviation	4.27	0.89	2.54
Coefficient of Variation (%)	23.11	4.83	9.50
Shell height			
Mean (mm)	63.05	63.41	69.73
Standard Deviation	5.24	3.11	3.95
Coefficient of Variation (%)	8.31	4.90	5.66

The juveniles from each selected and control lines were settled on netlon mesh and after 2 weeks of growth in the laboratory, transferred to the field (Quetalmahue) until they were ready for tagging (5 mm). After 15 weeks of growth in the field, the juveniles from each line were individually labeled and transferred randomly in pearl nets to 3 different aquaculture farming sites. Hueihue Bay, located 500 m from a commercial oyster farm; and Quetalmahue Gulf and Putemún Channel, located around a mussel farm, all of them within the Chiloé Island (Fig. 1).

Live weight and shell height were monitored at 10, 14, 18, and 22 mo of age using an A&D portable balance (± 0.01 g) and vernier calipers (± 0.1 mm).

Analysis of Variance (ANOVA) including the effects of location, group (selected and control), and their interactions were carried out for live weight and shell height at the four life stages using the SYSTAT 5.1 statistical package (Wilkinson 1991). Log-transformations were used to normalize the data where appropriate. The response to selection and realized heritability estimates and their standard errors were calculated according to Falconer (1989), Becker (1992), and Hadley et al. (1991). A statistical comparison ($P \leq 0.05$) of differences in heritability values (Student's t test) was done.

RESULTS

Growth data at 10, 14, 18, and 22 mo of age for the traits live weight and shell height at 3 locations are presented in Table 2. From the mean of each group (control and selected) it can be seen that there are differences in both traits among the three different locations. The ANOVA results (Table 3) show that for live weight

TABLE 4.

Mytilus chilensis. Realized heritability estimates (h^2) and their standard errors (\pm SE) for the traits "shell height" and "live weight" at 22 months old grown at 3 geographically separated mussel farms.

	Shell Height		Live Weight	
	h^2	SE	h^2	SE
Hueihue	0.32	± 0.017	0.38	± 0.020
Putemun	0.49	± 0.024	0.54	± 0.018
Quetalmahue	0.48	± 0.016	0.35	± 0.015

and shell height, there is a significant effect of "location" (three locations) and "group" (selected and control) sources of variance. There were no significant effects of the location by group interaction term. A significant response to selection for the direct selected trait "live weight" was found at all ages monitored (see Table 3). The standardized responses fluctuated between 0.77 and 0.05 units of SD from the control. A correlated response for the trait 'shell height' was detected (see Table 3). The response measured as standardized Index did not differ significantly among the different localities ($P > 0.05$).

The realized heritability estimates for the traits "live weight" and "shell height" at 22 months of age exhibited values significantly greater than zero in all three locations (Table 4). Heritabilities for live weight did not differ significantly between Hueihue and Quetalmahue locations ($P > 0.05$) while Putemún and Quetalmahue showed similar heritabilities for shell height ($P < 0.05$); therefore even when growth rates differed significantly among environments, the additive genetic variance did not vary from location to location, with the exception of Putemún and Hueihue for live weight and shell height respectively.

DISCUSSION

Live weight and shell height varied significantly among environments in which the offspring were raised (see Table 2 and 3). This implies that environmental variation plays a large role in determining these growth traits. The location \times group interaction (G \times E) was not significant for either of the two traits (see Table 3), meaning that although there was significant variation among environments for each trait, the overall rank of each group in each environment was unchanged across sites.

There was a significant and steady response to selection in both traits across the environments. These results are in accordance with those reported by Crenshaw et al. (1991), for *Argopecten irradians concentricus*; Bustos et al. (1991) and Toro et al. (1994), for *Ostrea chilensis*; and Nell et al. (2000), for *Saccostrea glomerata* were a positive response to selection was found. Toro and Newkirk (1991) working with *O. chilensis* reported also a significant response to

reduce the same trait, comparing a low selected line against an unselected control line.

The realized heritability estimates in both traits 22 months of age (see Table 4), were significant across the three environments measured, although, no significant genotype \times environment interaction for these traits were detected (see Table 3). Therefore, a selection intensity applied to these traits results in predictable changes in the phenotype values of the traits among environments (Falconer 1989). There are no reports on realized heritabilities on adult mussels, however, the heritability values obtained here are lower than those reported by Newkirk & Haley (1982), in *Ostrea edulis*; Lannan (1972), in *Crassostrea gigas*; Stromgren & Nielsen (1989) and Losee (1978), in *Mytilus edulis*. However, they are in accordance with those reported by Toro & Newkirk (1990), in *O. edulis*; Toro & Newkirk (1991), in *O. chilensis*; Wada (1986), in *Pinctada fucata martensii* ($h^2 = 0.47$ & 0.35 for shell width and shell convexity respectively); Hadley et al. (1991), in *Mercenaria mercenaria* ($h^2 = 0.43$ for growth rate); and also in line with values for production traits in livestock (Van Vleck 1987).

Using the realized heritability values obtained and applying a selection intensity of 1.755 that is equivalent to select the higher 10% of the population for the trait, the estimated mean change in live weight ranges between 2.6 % to 4.0 % and for shell height between 2.9 % to 4.5 % per generation. These values of response to selection for increasing the traits are lower than those given by Mallet et al. (1986) and Stromgren & Nielsen (1989) for *M. edulis* and Newkirk & Haley (1982) for *O. edulis*; these authors reported a large response to selection for growth to market size with an average of 23 % of gain over the controls.

The correlated response found for the trait "shell height" suggests a positive genetic correlation between the two traits. Very high genetic correlations between live weight and shell height have been reported ($r_a = 0.995$) for *O. edulis* (Toro & Newkirk 1990) and for *M. edulis* juveniles (Nielsen 1985).

The estimates of heritability for traits of economic importance such as live weight and shell height is essential in a long term breeding program to enhance the growth rate of the Chilean mussels. The quantitative genetic parameter estimates should be obtained under natural conditions and their constancy measured among different environments to be able to predict potential responses to selection (Mitchell-Olds & Rutledge 1986). Heritability values are essential for the purpose of predicting the genetic gain by selection. In common with previous studies of bivalves, our experiments demonstrate significant genetic variation in live weight and shell height, which may have implications for the biology of natural populations of *M. chilensis* as well as for commercial culture.

ABSTRACT The Pacific oyster, *Crassostrea gigas* (Thunberg), and the Portuguese oyster, *C. angulata* (Lamarck), are two closely related taxa. Although these two taxa were both introduced from Asia into Europe, one (*C. gigas*) was voluntarily introduced in the early 1970s, whereas the other (*C. angulata*) was presumed to be present in Europe for at least four centuries, but nearly disappeared because of disease. Few *C. angulata* populations remained in southern Portugal, Spain and Morocco and their putative origin was traced in Taiwan. The present paper reports evidence for its presence in Northern China. We reanalyzed recently published mitochondrial cytochrome oxidase C subunit I (COI) sequence data from presumed Dalianwan oysters (*C. talienwhanensis*) and compared them with those of *C. gigas* and *C. angulata*. Additionally, two new *C. angulata* haplotypes from Portugal were identified. The results clearly showed that some of the *C. talienwhanensis* sequences cluster with *C. angulata* sequences. The relative divergence between *C. gigas*, *C. angulata*, and *C. talienwhanensis* haplotypes indicated that *C. angulata*-like oysters are present in northern China. This opens new perspectives in terms of genetic resources and population genetics of *C. gigas* and *C. angulata*, two oyster species of aquacultural importance.

KEY WORDS: cupped oysters, *Crassostrea angulata*, *Crassostrea gigas*, *Crassostrea talienwhanensis*, cytochrome oxidase C subunit I gene, phylogeography

INTRODUCTION

The phenotypic plasticity of oysters and their wide range of distribution are known to have led to numerous taxonomic misclassification or redundancy in species names. However, during the last decade, molecular tools have contributed in highlighting and resolving several of these cases. For example, Anderson and Adlard (1994) proposed that *Saccostrea commercialis* and *S. glomerata* should be regarded as synonymous taxa based on rDNA internal transcribed spacer sequence data. More recently, Kenchington et al. (2002) suggested that *Ostrea edulis* and *O. angasi* are conspecific. In addition, O'Foighil et al. (1999) confirmed the transoceanic range (New Zealand and Chile) of *O. chilensis* using mitochondrial COI sequence data and proposed that dispersal by rafting was the most likely explanation for this distribution. Similarly, the mangrove oyster *Crassostrea gasar* was shown to be present not only along the coasts of Western Africa but also along the Atlantic coasts of South America where some specimens had been wrongly described as *C. rhizophorae* (Lapègue et al. 2002).

In this context, the relative taxonomic status of the Portuguese oyster, *C. angulata*, and the Pacific oyster, *C. gigas*, may be considered as a case study. *C. gigas* and *C. angulata* were classified as two different species by Thunberg in 1793 and Lamarck in 1819, respectively. This classification was chiefly due to apparently separated geographical distribution of the two species, because *C. angulata* was described in Europe and *C. gigas* in Asia. However, following morphologic comparison (Ranson 1948), experimental hybridization (reviewed by Gaffney & Allen 1993, Huvet et al. 2001, Huvet et al. 2002) and allozyme data (Mathers et al. 1974, Buroker et al. 1979, Mattiucci & Villani 1983), the authors concluded that there was only a single species, grouping Portuguese and Pacific oysters. Yet, significant phenotypic differences between the two taxa were observed, in terms of production yield (Bougrier et al. 1986, Héral 1986, Parache 1989, Soletchnik

et al. 2002), and eco-physiologic characteristics (His 1972, Goulletquer et al. 1999, Haure et al. 2003). Furthermore, differences have now been observed (1) from karyotype analyses (Leitão et al. 1999b) although these two taxa exhibited a close genetic similarity in comparison with other cupped oyster species (Leitão et al. 1999a); (2) in the genetics of the two taxa based on the mitochondrial COI gene (Boudry et al. 1998, O'Foighil et al. 1998) and nuclear microsatellites (Huvet et al. 2000).

The introduction of the Pacific oyster was relatively well documented because it was a recent voluntary introduction. Hence, the introduction of *C. gigas* from Japan into Europe was made in the early 1970s to replace the Portuguese oyster in the shellfish industry (Grizel & Héral 1991) that nearly disappeared probably due to an iridoviral disease (Comps 1969). As indicated by its common name, the Portuguese oyster, was believed to originate from Portugal or at least southern Europe. However, results from nuclear and mitochondrial DNA studies (Boudry et al. 1998, O'Foighil et al. 1998, Huvet et al. 2000) suggested an explanation for the separated geographical distribution of these genetically closely-related taxa by supporting the hypothesis of the introduction of *C. angulata* from Asia (and more precisely Taiwan) to the Portuguese coast by merchant ships during the 16th century. Until now, no *C. angulata* specimens were observed in any other Asian location (see Lam et al. 2003, Boudry et al. 2003).

China is the country with the largest *C. gigas* production (in 1997: Mainland China: 2.3 10⁶ metric tonnes, Taiwan: 24 10³ metric tonnes, Hong Kong: 66 metric tonnes, according to FAO, 1999). However, Guo et al. reported in 1999 that it is not *C. gigas*, but another species, *C. plicatula*, that accounts for the main 50% to 60% of the production, *C. ariakensis* for 20% to 30% and *C. gigas* for only 10% to 20%. Qi (1989) also cited the Dalianwan oyster (*C. talienwhanensis*) as of commercial importance after the Zhe oyster (*C. plicatula*) and the Suminoe oyster (*C. ariakensis*) (Qi 1989). Many other different taxa have been reported along Chinese coasts and species identification is often uncertain. In Northern China, *C. talienwhanensis*, *C. plicatula* and *C. gigas*

*Corresponding author. E-mail: Sylvie.Lapegue@ifremer.fr

were considered as sibling species (Liu & Dai 1998). In the East and South China, at least nine species have been described (Bernard et al. 1993). Recently, a new species was described in Hong Kong (Lam & Morton 2003, Boudry et al. 2003). Finally, a recent study based on mitochondrial DNA sequences showed that *C. talienwhanensis* specimens from Northern China were genetically close to *C. gigas* specimens which suggested that the Dalianwan and Pacific oysters belong to the same species (Yu et al. 2003). Similarly, their results suggested that *C. plicatula* and *C. ariakensis* are closely related.

In the present paper, we compared DNA sequence data of *C. gigas*, *C. talienwhanensis*, and *C. angulata* to establish their genetic relationships. To do so, we reanalyzed the mitochondrial COI sequence data of *C. talienwhanensis* specimens from Yu et al. (2003) and compared with those of known haplotypes from *C. gigas*, *C. angulata* (Boudry et al. 1998) and two newly identified *C. angulata* haplotypes.

MATERIALS AND METHODS

New *Crassostrea angulata* Sequence Data

A total of 218 cupped oysters from Portugal were sampled in October of 2002 from 2 locations, 109 in the Sado estuary (Monte da Pedra site: 38°25'N, 8°39'W) and 109 in the Mira estuary (Roncão Velho site: 37°42'N, 8°44'W). DNA extraction of ethanol-preserved gill fragments was performed by a phenol/chloroform method, as described by Moore (1993). A partial COI fragment was amplified using the primers and conditions detailed in Folmer et al. (1994). Polymorphism was first studied using restriction enzymes as described by Boudry et al. (1998). Some of these PCR products were sequenced as described by Boudry et al. (2003). All the novel sequences have been submitted to the EMBL nucleotide sequence database.

DNA Sequence Analysis

The COI sequences of the new haplotypes, together with some sequences already obtained for *Crassostrea gigas* and *C. angulata*

(Accessions AJ553901, AJ553902, AJ553903, AJ553904, AJ553905; Boudry et al. 2003), *C. virginica*, *C. ariakensis*, and *C. sikamea* (Accessions AF152566, AF152569, AF152568; O'Foighil et al. 1998) and *C. talienwhanensis* (Yu et al. 2003) were aligned with CLUSTALW (Thompson et al. 1994). Pairwise sequence divergences between species were estimated with the DNADIST program in PHYLIP (Felsenstein 1989) according to Kimura's two-parameter model (Kimura 1980). Phylogenetic analyses were conducted using the program FITCH. Bootstrap analysis with 100 replicates was performed with the SEQBOOT and CONSENSE programs.

RESULTS

PCR-amplified fragments from the COI gene were obtained for 218 individuals from the newly sampled Portuguese populations. The PCR-RFLP analysis detected 2 new haplotypes, which were called F and G here. Haplotype G lacked a *Sau3A* restriction site when compared with the others haplotypes of *Crassostrea gigas* and *C. angulata* described by Boudry et al. (1998). For haplotype F a new restriction site was observed using *MseI* when compared with the same haplotypes. These new haplotypes are rare, each one being present in one of the two populations: the frequency of haplotype F is 5% in Mira and the frequency of haplotype G is 2% in Sado. The COI sequences of haplotypes F and G, together with haplotype J—that had been described by Boudry et al. (2003), but not sequenced—were respectively registered as Accessions AY397685, AY397686, and AY455664. We compared the sequences of these haplotypes, F, G, and J, with those of haplotypes from *C. gigas* (haplotype C, D, and E; Boudry et al. 2003), *C. angulata* (haplotype A and B; Boudry et al. 2003), and *C. talienwhanensis* (haplotype talienw1, talienw2, talienw3, talienw4, and talienw5; Yu et al. 2003). The multiple alignment showed that haplotypes C and talien1 had exactly the same sequence. The distances computed after this alignment is presented in Table 1. The phylogenetic tree obtained from sequence divergence of the COI fragment according to Kimura's model (Kimura

talien1 and haplotype C have the same COI sequence.

1980) is given in Figure 1. The 12 haplotypes clustered into 2 groups (100% bootstrap *P* value) with a divergence varying from 2.2% to 3.7% depending the pairs of haplotypes being compared. One group encompassed the *C. gigas* haplotypes (C, D, and E) and the *C. talienwhanensis* haplotypes (talienw1, talienw2, and talienw3). The second group included the *C. angulata* haplotypes (A, B, J, F, and G) and the *C. talienwhanensis* haplotypes (talienw4 and talienw5). The nucleotide divergence within the first group varies from 0.2% to 0.5% and in the second group from 0.2% to 1.7%. *C. sikamea* and *C. ariakensis*, two other Asian cupped oysters species, respectively exhibited about 10% and 16% divergence with the *C. gigas* and *C. angulata* haplotypes. The American oyster, *C. virginica*, showed about 26% divergence with the *C. gigas* and *C. angulata* haplotypes and was considered as an outgroup.

DISCUSSION

The geographic distribution of the closely related taxa *Crassostrea gigas* and *C. angulata* in southwestern Europe is now well documented, so is the genetic variability within the populations and the genetic differentiation between the populations. *C. gigas* was observed in northern Europe bordered by the headland of northern Spain (La Corogne) in the south. *C. angulata* was observed in southern Spain, Portugal, and Morocco (Boudry et al. 1998, Fabioux et al. 2002, Huvet et al. 2004). According to the

grouping of the haplotypes observed here, haplotype F and G, detected in the new samples from the Mira and Sado Portuguese populations, can be considered as two new *C. angulata* haplotypes. This is confirmed by the divergence values that are of the order of those reported by Boudry et al. (2003): less than 0.5% for the *C. gigas* group compared with 0.2% to 0.5% in this study, and less than 1.1% for the *C. angulata* group compared with 0.2% to 1.7% in this study. When observing the results for the *C. talienwhanensis* haplotypes from Yu et al. (2003), talienw1 (identical to haplotype C), talienw2 and talienw3 are grouped with the *C. gigas* haplotypes, and talienw4 and talienw5 with the *C. angulata* haplotypes. Consequently, oysters of talienw1, talienw2 and talienw3 can be considered as *C. gigas*, as proposed by Yu et al. (2003), and the others (oysters of talienw4 and talienw5) can be considered as *C. angulata*. This partly confirms that the Dalianwan oyster, described by Zhang and Lou (1956), is another name for the Pacific oyster in China (Li & Qi 1994), but also supports that *C. talienwhanensis* being considered as *C. angulata*. After the evidence of the presence of *C. angulata* in Taiwan (Boudry et al. 1998), this species is now found existing in the northern China (Dalian, Liaoning province and Rongcheng, Shandong province) suggesting a broader Asian geographical distribution. Additionally, it should be noted that the cupped oysters specimens found in Hong-Kong (Lam et al. 2003, Boudry et al. 2003) and considered as belonging to a putative new taxa, cannot be considered as *C. talienwhanensis*.

Figure 1. Phylogenetic trees obtained from sequence divergence of a 551 nucleotide mitochondrial COI DNA fragment according to Kimura's model (Kimura 1980) for *C. gigas*, *C. angulata*, and *C. talienwhanensis* haplotypes. talienw1 to 5 correspond to the haplotypes described by Yu et al. (2003). The sequences of haplotypes A, B, C, D, and were described in Boudry et al. (2003). The sequences of *C. ariakensis*, *C. sikamea* and *C. virginica* were obtained from O'Foighil et al. (1998). The sequences of haplotypes F, G, and J were described in this study. *C. virginica* was used as an outgroup. Numbers on the branches indicate bootstrap *P* values.

In total, 11 *C. angulata* COI haplotypes (A, B, and J from Boudry et al. 1998; angul1, angul2, angul3, and angul4 from O'Foighil et al. 1998; talienw4 and talienw5 reanalysed from Yu et al. 2003; F and G in this study) and 5 *C. gigas* COI haplotypes (C, D, and E from Boudry et al. 1998; talienw1 (identical to haplotype C), talienw2, and talienw3 reanalysed from Yu et al. 2003) have now been described. Interestingly, using relatively equivalent amount of research on both taxa, the level of variability of *C. gigas* appears to be lower than that of *C. angulata* for the COI sequence. Furthermore, studies based on allozyme data by Buroker et al. (1979) also showed a high genetic variability in *C. angulata*, from Portuguese populations, relative to other *Crassostrea* species. More data are needed from other mitochondrial and nuclear markers, but this high genetic variability observed in *C. angulata* opens interesting perspectives for the development of conservation programs for this taxa in Europe. Consequently this also underlines the importance of *C. angulata* as a potentially useful genetic resource for *C. gigas* aquaculture.

Although the two 16S haplotypes described for the 10 *C. talienwhanensis* individuals from Yu et al. (2003) study were each found in 2 different sampling locations (Dalian & Rongcheng), the 5 COI haplotypes (talienw1 to talienw5) distribution indicated that

C. gigas and *C. angulata* co-occur in the two sampled locations. Hence, one individual has the talienw1, one the talienw2, one the talienw3, four the talienw4, and three the talienw5 haplotypes. This result needs to be confirmed, because the number of samples (5 in each location) is low. It would be of particular interest to focus on the sympatric status of these two taxa in this region as it was done in Southern Europe. In Portugal, there was evidence for hybridization between *C. angulata* and *C. gigas* in the wild where the two taxa are in contact due to recent transportation of *C. gigas* stocks for aquacultural production (Huvet et al. 2004). An extensive sampling protocol is clearly needed in Northern China to investigate this hybridization in the native region of these two taxa, and, more generally, their relative evolutionary history.

ACKNOWLEDGMENT

ABSTRACT In this work we studied the actual coverage, distribution patterns and ecologic effects of the introduced oyster *Crassostrea gigas* 20 y after their introduction to the Northern Argentinean Patagonia (Bahía Anegada; 39°50'S to 40°40'S and 61°59 to 62°28 W). Using satellite imagery and field and aerial inspections we found 10 oyster beds that cover less than 0.05% of the bay intertidal (area covered: 36.45 ha). These beds are restricted to intertidal zones with superficial hard substrata (limestone outcrops). Most epifaunal organisms (the crabs *Cyrtograpsus angulatus*, *Chasmagnathus granulatus*, the isopod *Melita palmata*, and the snail *Heleobia australis*) showed higher densities inside oyster beds compared with outside and experiments showed that artificially deployed oyster beds increased the densities of their at three intertidal zones (high intertidal marsh, low intertidal marsh, and low intertidal with hard substrata) and also increased densities of infaunal organisms (the polychaetes *Laconereis acuta*, *Nephtys fluviatilis*, and the priapulid *Priapulid tuberculatospinosus*) at the low intertidal with hard substrata. This may be the result of increasing habitat structure and refuge for epifaunal organisms, and enhancement of deposition and sediment stability that may benefit infaunal organisms. Densities bird species (Local species: *Larus dominicanus*, *Haematopus palliatus*; Regional migratory shorebird: *Charadrius falklandicus*; Long range migratory shorebirds: *Pluvialis dominica*, *Calidris canutus*, *Tringa flavipes*) were higher inside oyster beds compared with similar zones without oysters, which may be the result of higher prey availability. Foraging rate was also higher for some of these species (*P. dominica*, *C. falklandicus*). However, due to the limited availability of hard substratum the distribution of oysters is small. In conclusion, no negative effects were observed as a result of this introduction. There was an increase in species abundance and the area was preferred by local and migratory bird species, which also showed higher feeding rates.

KEY WORDS: biologic invasions, *Crassostrea gigas*, ecosystem engineers, migratory shorebirds

INTRODUCTION

The effect of invasive nonindigenous species on native communities had become a major problem in conservation biology (Lodge 1993, Mack et al. 2000, Bax et al. 2001, Byers et al. 2002) mainly because their negative effects on native species, communities and ecosystems (e.g., Vitousek & Walker 1989, Settle & Wilson 1990, Vitousek 1990, Spencer et al. 1991, Carlton 1992, Petren & Case 1996, Juliano 1998, Mack et al. 2000, Byers 1999, Byers 2000, Byers et al. 2002). Marine ecosystems are especially vulnerable to invasive species (Carlton 1996) showing some dramatic effects on biologic diversity and productivity (Bax et al. 2001). However, little attention has been paid to the role of physical ecosystem engineer species (*sensu* Jones et al. 1994) as habitat modifiers when introduced to new habitats. The change of the physical structure of the ecosystem is not currently accounted for in the evaluation of invader's impact (Crooks 2002), but a large effect in the native community is expected when the invader change habitat complexity or heterogeneity (Posey 1988, Crooks & Khim 1999, Crooks 2002, Bruno et al. 2003).

Physical ecosystem engineer species (*sensu* Jones et al. 1994) that create biogenic structure are known to affect community structure (Jones et al. 1997). This effect is because biogenic structure can affect competitive interactions (Fletcher & Underwood 1987), modify the relative importance of predation (Gilinsky 1984, Orth et al. 1984, Dean & Connell 1987, Schwindt et al. 2001, Hamilton

& Nudds 2003) and, ameliorate physical stress (Nixon et al. 1971) and disturbance (Whorff et al. 1995), generally leading to an increase in the density and diversity of associated organisms (Gilinsky 1984, Downes et al. 1998, Zühlke 2001, Bolam & Fernandes 2003, but see Kelaher 2003). Oysters are a good example of substrate and structure creators (see Jones et al. 1997, Gutiérrez et al. 2003), serving as refuge for numerous mobile and sessile species and having a large effect on community structure (Ulanowicz & Tuttle 1992, Kennedy 1996, Dumbauld et al. 2000, Meyer & Townsend 2000, Lenihan et al. 2001) but oysters are also a good example of invasive species in marine and estuarine environments (Carlton 1992, Reise 1998), usually introduced for aquaculture purposes (Carlton 1992, Shatkin et al. 1997, Wasson et al. 2001, Miller et al. 2002). Although ecologic impacts of mollusk farming are known to be small compared with other forms of aquaculture (Naylor et al. 2000), there are several examples of native community modification as a result of *Crassostrea* spp. introduction by direct competition with native species (Shatkin et al. 1997, Reise 1998), by spreading other invasive species (Carlton 1992, de Montaudouin et al. 1999, Byers 1999, 2000, Wolff and Reise 2002), diseases (e.g., Grizel & Héral 1991, Mann et al. 1991, Shatkin et al. 1997, Wolff & Reise 2002), and by decreasing benthic oxygen levels (Castel et al. 1989).

The Pacific Oyster *Crassostrea gigas*, a species endemic from Japan, is today the most successful oyster in commercial cultivation of hatchery-produced seed and is the basis of the largest oyster fisheries in the world (Mann et al. 1991, Reise 1998). *C. gigas* has been extensively introduced outside its native range for culture purposes, and established in the field (Mann et al. 1991, Carlton

*Corresponding author. E-mail: cescapa@mdp.edu.ar

1992, Shatkin et al. 1997). In South America, *C. gigas* was introduced on the Pacific Ocean in Chile and Peru (Winter et al. 1984), and in the Atlantic in Brazil and Argentina (Pascual & Orensanz 1996, Orensanz et al. 2002). In Argentina, this species was illegally introduced during 1982 in Bahía Anegada (39°50'S to 40°40'S and 62°10'W; see Figure 1; Orensanz et al. 2002, Penchaszadeh et al. 2003). A small stock of commercial size of *C. gigas* (ca 500 individuals) imported from Coquimbo (Chile), with gastronomic purposes, were introduced to the southern part of Bahía Anegada with the purpose of implementing an aquaculture production (Orensanz et al. 2002). After a year of experimentation, the remainder small stock was abandoned but they established in the field (Orensanz et al. 2002, Penchaszadeh et al. 2003).

Although there are several conflicts rising from the invasion of *Crassostrea gigas* on northern Patagonia, one important concern is related to conservation of shorebird habitats. The SW Atlantic intertidals are main stopover sites of migratory shorebirds that breed in the northern hemisphere and spend their winter in the southern hemisphere (see Botto et al. 1998). However, the distribution patterns and coverage extension of *C. gigas* on the intertidal and its effects on the benthic community and shorebirds remain unknown. In this context, the main purpose of this research is to evaluate the number, distribution, and extension of *C. gigas* beds today and to evaluate, by sampling and by field experiments, its effects on the benthic community and shorebird habitat use.

MATERIALS AND METHODS

The study was performed in Bahía Anegada (Fig. 1; see Spalleti & Isla 2003 for full description) from December 2001 to November 2003. This is a large embayment (2371 km²) affected by a low amplitude (≤ 1.5 m) semidiurnal tidal regimen.

Given that oysters showed a wide distribution, an analysis of satellite imagery were performed to identify oyster beds and evaluate their spatial distribution. The satellite imagery used was recorded by Enhanced Thematic Mapper plus sensor on board Landsat 7. It records radiation with a nominal spatial resolution of approximately 30 m for bands 1–7, and 15 m for band 8 (panchromatic). Because the tide level is an important factor in saltmarshes and higher levels can mask some habitats, in this study only the image with the lower tide level of a pool of satellite images was selected. The image selected was from 15 January 2002 and was provided by the Argentinean National Commission of Space Activities (CONAE).

To remove the geometric distortions in Landsat imagery, image was geocoded to a UTM Gauss Kruger coordinate system using a first order transformation and nearest neighbor resampling. The root-mean squared error achieved after resampling was lower than 1.5 pixels in all bands. We used map points to geometric corrections. Points were acquired from topographic maps of the Argentinean Army Geographic Institute (IGM; scale 1:50,000).

The south portion of Bahía Anegada was exhaustively searched by walking and the location of oyster beds and different types of

Figure 1. Location and dimension of oyster beds in Bahía Anegada (Argentina). Large oyster beds are shown in black, and smaller ones are indicated by arrows. BB, Bahía Blanca and GSM, Golfo San Matías. Low grey represent intertidal habitat.

environments along the intertidal were registered (position obtained by GPS). A spectral signature analysis of the different kinds of intertidal habitats (tidal flats, saltmarshes dominated by *Spartina alterniflora* Loisel and saltmarshes dominated by *Sarcocornia perennis* (Miller) (formerly *Salicornia ambigua*) were compared with the spectral signature of a known oyster bed. Bahía Anegada intertidal has a mixture of limestone outcrops, sand, silt, and rolling stone bottoms. This variation in substrata, and the variation in water content as a result of field irregularities, generated a bias spectral response that did not allow us to perform a correct classification using common supervised and unsupervised classification methods because of greatly overestimated oyster bed cover. Given this problem, we used a visual analysis of the image, utilizing the Landsat ETM+Panchromatic band (spectral range 520–00 nm), that have a 15 m spatial resolution and allow a good identification of the known oyster beds.

In the Landsat ETM+Panchromatic band, known oyster beds have a particular dendritic pattern that make them conspicuous in the intertidal. This characteristic pattern was used to search for similar structures to make a preliminary oyster beds map. Then, an exhaustive aerial inspection (flying between 60 and 100 m altitude and between 100 and 150 km per hour) of Bahía Anegada coast and islands was done during low tide to verify the presence of oyster beds. No new oyster beds were found but some structures previously identified as oyster beds were discarded. Discrimination of land, intertidal and water was done using the Idrisi32 Maximum Likelihood Software module. The final map (Fig. 1) was done by adding the identified oyster beds to the thematic map.

To study the distribution patterns in relation to intertidal level, transects (100 m) perpendicular to the shoreline were performed (spaced by at least 50 m). In each transect, the number of oysters in 1 m² were counted every 0.4 m of intertidal height. The null hypothesis of no differences in oyster densities between tidal levels was analyzed with 1-way ANOVA (Zar 1999). To evaluate the type of substrate used by oysters, the depth at which the hard substratum (i.e., limestone outcrops) was located was measured by pushing a 1.5 m iron stick and noting the buried length of the stick when it touch the hard substratum, and the number of oysters (m⁻²) were counted. The null hypothesis of no relation between hard substratum depth and oyster densities was analyzed with correlation analysis (Zar 1999).

To evaluate whether there is a relation between oyster beds and densities of epifaunal organisms, samples of 0.25 × 0.25 m were assigned inside and outside oyster beds. In each sample, epifaunal organisms were counted and identified to the lowest taxonomic level possible. For each taxa, the null hypothesis of no differences in densities of organisms were analyzed with *t*-test (or Mann-Whitney when necessary, Zar 1999). To evaluate if there was any relation between oyster densities and the densities of the predominant native grapsid crab *Cyrtograpsus angulatus* Dana, a species that is known to be strongly and positively affected by biogenic structure (see Schwindt & Iribarne 2000, Schwindt et al. 2001, Mendez Casariego et al. 2004), a different sample design was used. The number of oysters and crabs were counted in 83 sampling units of 1 m², randomly chosen along the intertidal. The null hypothesis of no relation between densities of oysters and crabs were evaluated with correlation analysis. Similarly, to evaluate the relation between oyster beds and densities of the snail *Helicobia australis*, the intertidal substrate was divided into 3 zones (High = 1.3 m above the lower tidal level (ALTL), medium = 0.7 m ALTL and low = 0.2 m ALTL). In each zone, the number of snails in 25

samples of 0.2 × 0.2 m was counted in pools inside and outside oyster beds. For each intertidal level, the null hypothesis of no differences in snail densities between sites was evaluated with *t*-test (Zar 1999).

To experimentally evaluate the effect of *Crassostrea gigas* on natural community on the high marsh, the low marsh and the low intertidal with hard substrata, 60 square plots (1 m²), 20 in each zone, were randomly chosen on January 2002. Each plot was assigned to one of the following treatments; (1) artificial oyster bed or (2) control. Artificial oyster bed treatments were done by transplanting oysters from natural oyster beds to the plots. These oysters were washed with seawater to eliminate epifauna before transplanting. After 11 mo, epifaunal organisms were counted and classified on a 0.25 × 0.25 m square from the center of the plot. In each plot, a core sample (35-cm depth, 15-cm diameter) was also taken. Infaunal organisms were separated by sieving the samples through a 0.5-mm screen. Organisms were counted and classified to the lowest taxonomic level possible. The null hypotheses of no differences in densities of organisms of each species between treatments (with and without oysters) for each intertidal zone were analyzed with *t*-test or nonparametric Mann-Whitney test (Zar 1999).

One of the main concerns in the region came from the potential effect of oyster beds on habitat use by birds, mainly neotropical migratory shorebirds. To evaluate differential use of areas by shorebirds, 3 sites were selected at the SW part of the bay (Isla Jabali, Fig. 1 lower right) each one had oyster reefs and nearby areas without oysters. Each bed had a mean density of 47.4 oysters m² (SD = 12.3) and a mean surface area of 1 ha (Borges 2002, Penchaszadeth et al. 2003). Areas were selected keeping similar characteristics such as tidal level, slope and compass orientation (NW-SE) and known to be used by shorebirds. In each area, a telescope (18 × 36) was used to perform censuses from December 2001 to April 2002 (this period represent the entire migratory season). In each census, individuals were identified and the percentage of them feeding in each area was calculated. Abundance of each shorebird species was compared between sites and months with repeated measures ANOVA (Neter et al. 1990). To evaluate whether there is a relationship between the oyster beds and the shorebird foraging rate and efficiency, focal observations (using a 18 × 36 telescope) were performed. Each bird was observed for a period between 5 and 10 min. Before the observations, and based on a previous sampling, a list of all acts to be recorded was defined (walk, pause, peck, and capture of item) and maintained during the study to ensure standardized observations. The number of probes per minute and the proportion of probes resulting in successful prey capture were calculated. Differences in rate of consumption and foraging efficiency between areas were evaluated independently for each bird species with *t*-test (Zar 1999).

RESULTS

A total of 10 oyster beds were detected, 3 of small size (size range 0.09–0.36 ha), 6 of medium size (size range 1.62–5.67 ha) and 1 large bed (size 16.38 ha), all of them located in the southern part of the bay (Fig. 1). Oyster beds cover a total of 36.45 ha, which is less than 0.05% of the Bahía Anegada intertidal (total intertidal area = 89,689 ha). Both aerial and walk inspection reveals that besides the areas colonized by oysters there were no free superficial hard substrata along the intertidal.

Figure 2. Oyster densities across the intertidal. Squares represent means and bars standard deviation.

Spat were found attached to limestone outcrops, empty shells, shells of a native small mussel *Brachidontes rodriguezi* (d'Orbigny) and the basal portion of *Spartina alterniflora*. Oyster densities were higher in the middle and middle to low intertidal compared with other intertidal zones (ANOVA, $F_{19,177} = 56.404$, $P < 0.001$, Fig. 2). Moreover, there were no oysters in the low intertidal or in the subtidal. There was a negative correlation between hard substratum (i.e., limestone) depth and oyster densities ($r^2 = 0.597$, $n = 100$, $P < 0.001$) and there were no oysters in zones with hard substratum depths higher than 10 cm.

Inside the oyster matrix, the number of juveniles of the crab species *Chasmagnathus granulatus* Dana and *C. angulatus*, and the number of the polychaete *Laconereis acuta* (Treadwell) and the isopod *Melita palmata* (Montagu) were higher inside oyster beds but the number of the hermit crab *Pagurus criniticornis* (Dana), the snail *Heleobia australis* (d'Orbigny), and unidentified anemones were higher outside oyster beds (Table 1). There were no differences in number of the small mussels *Brachidontes rodriguezi* (d'Orbigny) (Table 1).

There was a positive correlation between oyster density and the density of the crab *Cyrtograpsus angulatus* ($r^2 = 0.27$, $df = 43$, $P < 0.001$). Similarly, densities of the snail *Heleobia australis* were higher in pools inside oyster beds along the 3 intertidal heights compared with pools outside oyster beds (high: $t = 9.79$, $df = 48$, $P < 0.001$; medium: $t = 3.402$, $df = 48$, $P < 0.005$; low: $t = 2.49$, $df = 48$, $P < 0.05$; Fig. 3).

In the high marsh, the number of the small mussels (square root transformed data; $t = 8.63$, $df = 18$, $P < 0.001$), anemones (log

transformed data; $t = 2.38$, $df = 18$, $P < 0.05$) and the crab *Cyrtograpsus angulatus* (log transformed data; $t = 7.32$, $df = 18$, $P < 0.01$) were higher in artificial oyster beds plots compared with control plots. The amphipods *Corophium* sp. and crabs of the species *Chasmagnathus granulatus* were only present in the artificial oyster bed plots. In contrast, the number of snails (*Heleobia australis*) was higher in the control plots ($Z = 2.86$, $N_1 = N_2 = 10$, $P < 0.005$). In the low marsh, there were no differences in the number of mussels between treatments ($t = 0.45$, $df = 18$, $P > 0.5$). Anemones, amphipods, polychaetes and, the crabs *C. angulatus*, *C. altimanus* Rathbun and *C. granulatus*, were present only in the artificial oyster bed plots. *H. australis* was present only in control plots. In the low intertidal, mussels and the crab *C. angulatus* were present only in artificial oyster bed plots. Inside the sediment, there were no differences in the number of mussels ($Z = 1.51$, $P > 0.1$), polychaetes of the species *Laconereis acuta* ($Z = 1.57$, $P > 0.1$) and *Neptilyx fluviatilis* Monro ($Z = 0.1$, $P > 0.5$), and the priapulid *Priapululus tuberculatospinosus* Baird ($Z = 0.1$, $P > 0.5$) between plots in the high marsh. In the low marsh, the number of polychaetes (*L. acuta*) were higher in control plots compared with artificial oyster bed plots ($Z = 1.256$, $N_1 = N_2 = 10$, $P < 0.05$) but there were no differences in the number of mussels between plots ($X_1 = 22.8$, $SD = 8.13$, $X_2 = 22.4$, $SD = 11.8$; $t = 0.09$, $df = 18$, $P > 0.9$).

The birds present during the study period were the Two Banded Plover *Charadrius falklandicus* (Latham), the American Golden Plover *Pluvialis dominica* (Müller), the Red Knot *Calidris canutus* (Linnaeus), the Lesser Yellowlegs *Tringa flavipes* (Gmelin), the American Oystercatcher *Haematopus palliatus* Temminck, and the Kelp Gull *Larus dominicanus* (Lichtenstein). For all these species (Fig. 4), densities inside oyster beds were higher than in the adjacent areas without oysters (American Oystercatcher: $t = 2.955$, $df = 60$, $P < 0.005$, the Two Banded Plover: $t = 5.772$, $df = 60$, $P < 0.001$, the American Golden Plover: log transformed data, $t = 12.667$, $df = 60$, $P < 0.001$) and the Kelp Gull: log transformed data, $t = 4.158$, $df = 60$, $P < 0.001$). The Red-knot ($X = 0.024$ ind* m^2 , $SD = 0.0199$) and the Lesser Yellowlegs ($X = 0.0023$, $SD = 0.0049$) were only present inside oyster beds. Foraging rate (Fig. 5) was higher inside oyster beds for the American Golden Plover ($t = 2.172$, $df = 31$, $P < 0.05$) and for the Two Banded Plover ($t = 2.294$, $df = 15$, $P < 0.05$) but there was no difference for the Oystercatcher (Mann-Whitney U -test, $Z_{adj} = 0.759$, $N_1 = 10$, $N_2 = 6$, $P > 0.1$) nor for the Red-Knot ($Z_{adj} = 0.039$, $N_1 = 17$, $N_2 = 5$, $P > 0.5$). There were no differences in foraging efficiency between sites (American Golden Plover: $t = 0.714$, $df = 31$, $P > 0.1$; Two Banded Plover: $t = 0.864$, $df = 15$, $P > 0.1$; Red Knot: $t = 0.857$,

TABLE 1.

Densities of species of epifauna inside and outside oyster beds. Density was expressed as individuals per sample unit (0.0625 m^2).

	Inside Oyster Beds	Outside Oyster Beds	d.f.	T or Z Value	P	Observations
<i>Chasmagnathus granulatus</i>	18.67 (7.75)	4.07 (5.35)	28	6.003	<0.001	t-test
<i>Cyrtograpsus angulatus</i>	3.2 (2.14)	0.4 (0.74)	28	5.065	<0.001	t-test, log

DISCUSSION

After more than 20 y of introduction, the Pacific oyster *Crassostrea gigas* has established in Bahía Anegada but covers a very small percentage ($\leq 0.05\%$) of their intertidal area. This contrasts with previous introductions of *C. gigas* around the world (and in wide array of environmental conditions), where *C. gigas* populations expanded in relatively short time (see Shatkin et al. 1997, Sumner 1980, Reise 1998). However, our evidences shows that in this area the distribution is limited by the lack of hard substratum, which is the result of a large sediment discharge from the Colorado River (see Spalletti & Isla 2003 for details). Although this river does not discharge now into the bay, the muddy sediments are still the dominant feature of this area.

We found oysters only in the intertidal zone with higher densities at the middle intertidal. This result contrasts from the pattern found in other sites, where densities of this species are higher in the low intertidal (Reise 1998). This pattern can result from the distribution of hard substrata (limestone outcrops). Oysters were present only in zones with superficial hard substrata; soft bottoms cannot support oysters on the surface (Reise 1998). The local oyster *Ostreola spreta* (d'Orbigny) (formerly known as *Ostrea spreta*) also settle on any hard surface (de Castellanos & Cabrera 1957, de Castellanos 1968), and is the dominant settling species in artificial collection of seed oysters deployed in this area (Borges et al. 2002). However, survival at the intertidal is low probably due low tolerance to higher temperatures (Stenzel 1971), even when

clusters of *C. gigas* offer a good settlement site (Penchazadeth et al. 2003). We have no information on the interaction between the two oysters, but the distribution pattern may in part be the results of competition. Thus, any effects of *C. gigas* on the local community are restricted to zones with superficial hard substrata (mainly limestone outcrop) in the middle intertidal.

Densities of the crabs *Cyrtograpsus angulatus* and *Chasmagnathus granulatus*, and of the amphipod *Corophium* sp. and the isopod *Melita palmata* were higher inside oyster beds and, as expected, experiments indicated densities of epifaunal organisms were higher in oyster beds than outside of the beds. The importance of availability of shelter and structure complexity on inter and subtidal community structure has long been recognized (e.g., Barshaw & Lavalli 1988, Fernández et al. 1993a, Fernández et al. 1993b, Gee & Warwick 1994, Moksnes et al. 1998, Lohrer et al. 2000, Robinson & Tully 2000, Jensen et al. 2002). Oyster shells are an important shelter creator with dramatic effects on crab densities (see Wainwright et al. 1992, Iribarne et al. 1995). The relationship between *C. angulatus* and habitat structure created by an introduced species has also been found in other SW Atlantic estuary (i.e., Mar Chiquita coastal lagoon) invaded by the reef building polychaete *Ficopomatus enigmaticus* Faubel (Schwindt & Iribarne 1999, Schwindt et al. 2001). In this case, oyster shells can increase crabs density not only by enhancing recruitment (see Fernández et al. 1993b) but also by decreasing adult predation risk (Mendez Casariego et al. 2004). In contrast, densities of the snail *Heleobia australis* and the hermit crab *Pagurus criniticornis* were lower inside oyster bed matrix. This can be because, for these two species, availability of shelter may not be a limiting factor (both

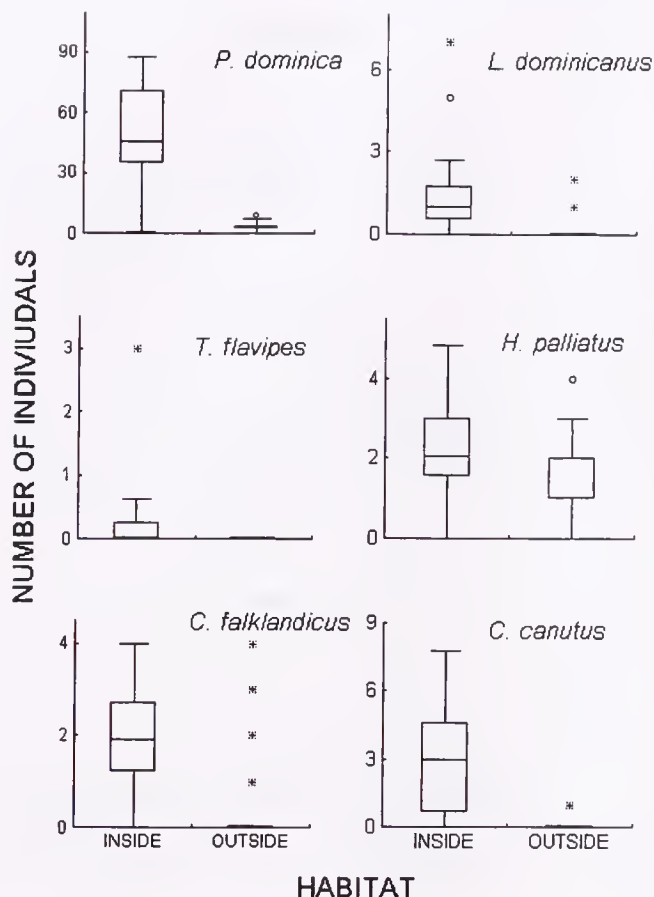

Figure 4. Average counts of number of individuals of different bird species using inside and outside oyster bed habitats. Circles represent outliers and asterisks are extremes.

species carried their own refuge) and they may be negatively affected by 3-dimension structure (see Kelaher 2003). Alternatively, predation risk may increase inside the oyster matrix because the higher abundance of predators such as crabs. Indeed, *H. australis* shells are usually found in *C. angulatus* stomach contents (P. Martinetto, pers. com.).

The increase of epifauna inside oyster bed plots may be the result of immigration, different mortality and recruitment (Crooks

& Khim 1999). Individuals of *C. granulatus* that occur in oyster bed plots were only adults suggesting colonization but not recruitment, in contrast, there were recruit and small juveniles of *C. angulatus* and all these stages plus adults of *C. altimanus* suggesting recruitment and colonization.

Densities and foraging rates of shorebirds were higher inside oyster beds and foraging efficiencies, whereas foraging inside or outside oyster beds, were the same. Wolff & Reise (2002) linked the decreases of the oystercatcher *Haematopus ostralegus* Linnaeus populations in the European Wadden Sea, with the introduction of *C. gigas*, and posterior transformation of mussel beds of *Mytilus edulis* d'Orbigny into oyster beds. In addition, bird foraging efficiency, while preying on intertidal invertebrates, are negatively affected by substrate heterogeneity (e.g., Common eiders on Rockweed beds; Hamilton & Nudds 2003; also Marsh 1986). Nevertheless, our results shows that prey abundance (particularly crabs and snails) were positively affected by the presence of biogenic structure created by oysters. Thus, as in mussel cultures (Caldow et al. 2003), higher prey abundance inside oyster beds may be influencing bird habitat choice by positively affecting their foraging rate.

Studies on the effect of naturalized pacific oyster beds on benthic communities also showed strong effects by decreasing O_2 on sediments as a result of organic matter enrichment (Castel et al. 1989, Nugues et al. 1996), by outcompeting local bivalve species (Shatkin et al. 1997, Reise 1998) and, by creating physical structure on otherwise flat zones (Castel et al. 1989). At Bahía Anegada the vascular plant *Spartina alterniflora* and the clumps of the small mussel *Brachydontes rodriguezi* offer settlement sites for this oyster (Borges 2001, Penchaszadeth et al. 2003). Interestingly, oysters and mussels can generate layers of settlement, forming clusters that sometimes can be used as settlement sites by *Ostreola spreta* (Borges 2001, Penchaszadeth et al. 2003). These changes in the physical structure of the ecosystem itself, was postulated as one form in which invaders can have strong ecosystem-level effects (Bertness 1984, Chapin et al. 1997, Crooks & Khim 1999, Crooks 2002) and is supported by some examples (e.g., Posey 1988; see also Crooks 2002 for a review). In contrast, other studies show an increase on macrofaunal abundance as a result of refuge creation (De Grave et al. 1998).

In summary, based in our observations on the distribution and coverage of the reefs of *C. gigas* and the expansion rates reported for other areas worldwide, the success of this oyster is low. However, in terms of the potential expansion, our result may be misleading, given that the distribution is controlled by the availability of substratum.

ACKNOWLEDGMENTS

The authors thank to Mr. M. Pereda for field help, Mr. A. Alzugaray (Municipality representative at San Blas) for general assistance, Dr. F. Isla for lending us satellite image processing software Idrisi 32, Dr. E. Spivak for helping with taxonomy and the Argentinean National Commission of Space Activities (CONAE) for providing us satellite images. This project was partially supported by Universidad Nacional de Mar del Plata, Fundación Antorchas (Argentina A013672 and 13900-13), National Geographic Exploration Grants (#6487-99), ANPCyT (1-7213) and CONICET (PIP 2851, all granted to O.I.). M. Escapa, P. Daleo, J. Alberti were supported by Doctoral scholarships from CONICET.

THE POTENTIAL OF AERIAL PHOTOGRAPHY FOR ESTIMATING SURFACE AREAS OF INTERTIDAL PACIFIC OYSTER BEDS (*CRASSOSTREA GIGAS*)

B. J. KATER* AND J. M. D. D. BAARS

Netherlands Institute for Fisheries Research, Centre for Shellfish Research, P.O. Box 77, 4400 AB, Yerseke, The Netherlands

ABSTRACT Pacific oysters were introduced into the Eastern Scheldt in 1964 for breeding purposes. The first spatfall of wild Pacific oysters was recorded in 1976, and a second larval outburst in 1982 definitely settled wild Pacific oysters in the Eastern Scheldt waters. Oyster beds on intertidal and subtidal areas have been growing since. The objective of this study is to research the potential of aerial photography for estimating surface areas of intertidal Pacific oyster beds. Black & white and false-color aerial photographs were used to locate Pacific oyster beds. For verification purposes, oyster bed contours were measured in the field. The accuracy of the method used was comparable with accuracies found in other studies, with a chance of underestimating the surface areas in the field. With aerial photographs of 1980 and 1990 the surface areas of Pacific oysters in both years were reconstructed, showing an increase in surface area of Pacific oyster beds. The study shows aerial photography has the potential to be an aid in surveying intertidal Pacific oyster beds.

KEY WORDS: aerial photography, *Crassostrea gigas*, reconstruction, Eastern Scheldt

INTRODUCTION

In the Eastern Scheldt Estuary (The Netherlands) flat oysters (*Ostrea edulis*) have been cultured since 1875 (Shatkin et al. 1997). The estimated stock size in 1962 was 120 million. After the severe winter of 1962/1963, which caused high mortality, the stock was reduced to 4 million oysters (Drinkwaard 1999). Searching for alternatives, Dutch oyster farmers introduced the Pacific oyster to the Eastern Scheldt in 1964. The Pacific oyster *Crassostrea gigas* (Thurnberg 1793) is native to Japan. The species has been introduced in several other areas, e.g. Australia, New Zealand, France, United Kingdom, Ireland and United States (Shatkin et al. 1997). The reasons for introduction include the economic pressures in the presence of diminishing wild fisheries resources, destruction of a fishery because of disease, or nonexistence of native fishery (Mann 1979).

The introduction of Pacific oysters in the Eastern Scheldt was found acceptable for 2 reasons. The first reason was the expected closure of the Eastern Scheldt with a dam, changing the Eastern Scheldt into a stagnant lake (Nienhuis & Smaal 1994) in which Pacific oysters would not survive. But in 1976 the Dutch government decided to build a storm surge barrier instead of a dam, leaving the Eastern Scheldt a tidal ecosystem (Nienhuis & Smaal 1994). The second reason was that offspring were not to be expected at the Eastern Scheldt latitude (Drinkwaard 1999). However, first spatfall on dike foos and jetties were recorded in 1976, and political pressure stopped importation of Pacific oysters in the following year. A second larval outburst in 1982 definitely settled wild Pacific oysters in the Eastern Scheldt waters (Drinkwaard 1999), and oyster beds on intertidal and subtidal areas have been growing since.

One of the main problems in the Eastern Scheldt concerning expansion of Pacific oysters is the potential interaction with commercially exploited species like cockles (*Cerastoderma edule*), blue mussels (*Mytilus edulis*), and cultivated oysters (*Crassostrea gigas*). Wild Pacific oysters can compete with these commercial species for food and space (Smaal et al. 2001). Although the growth of Pacific oyster distribution has been recognized as a possible problem, surveying oyster beds only started in 1999. To

reconstruct former relations between commercial shellfish species and expansion of the Pacific oysters, reconstruction of former surfaces with oyster beds is necessary. Remote sensing techniques like aerial photography can be helpful in this reconstruction. Aerial photography is often used as a tool for surveying e.g. estimating the population size of breeding Greylag Geese (Kristiansen 1997), green algal mats in the Skagerrak (Pihl et al. 1999), vegetation mapping in a tropical freshwater swamp in Australia (Harvey & Hill, 2001), seagrass coverage in Australia (Kendrick et al. 2002), and detection of dead or defoliated spruces in Finland (Haara & Nevalainen 2002).

The first objective of this study is to research the potential of aerial photography for estimating surface areas of intertidal Pacific oyster beds: how well can Pacific oyster beds be seen and distinguished from other structures on aerial photographs? The second objective is to reconstruct the surface areas of intertidal Pacific oysters from the past.

MATERIALS AND METHODS

Oyster Beds on Aerial Photographs

This study was performed on intertidal areas in the Eastern Scheldt (The Netherlands). Figure 1 shows the location of the study area.

Hardcopies of black & white photographs and false-color slides, made disposable by the National Institute for Coastal and Marine Management/RIKZ, were used in this study. Most photographs were taken on a scale 1:10000, but sometimes a scale of 1:5000 (Verdronken Land van Zuid-Beveland, 1980) or 1:20000 (Roggenplaat 1991 and 1999) was used.

The first reconstruction period is dated between the first and second Pacific oyster larval outbursts in the Eastern Scheldt. Most available photographs dated from 1980, so this year was chosen for reconstruction. All photographs were black and white. The second reconstruction period is dated after the second larval outburst of 1982. Based on photo availability, 1990 was chosen as the year to be reconstructed, and areas not photographed in 1990 were completed using photographs from 1989 and 1991. The last reconstruction dealt with the present situation—photographs taken in 1999 and 2000 were used.

Aerial photographs were digitalized for computer-aided analy-

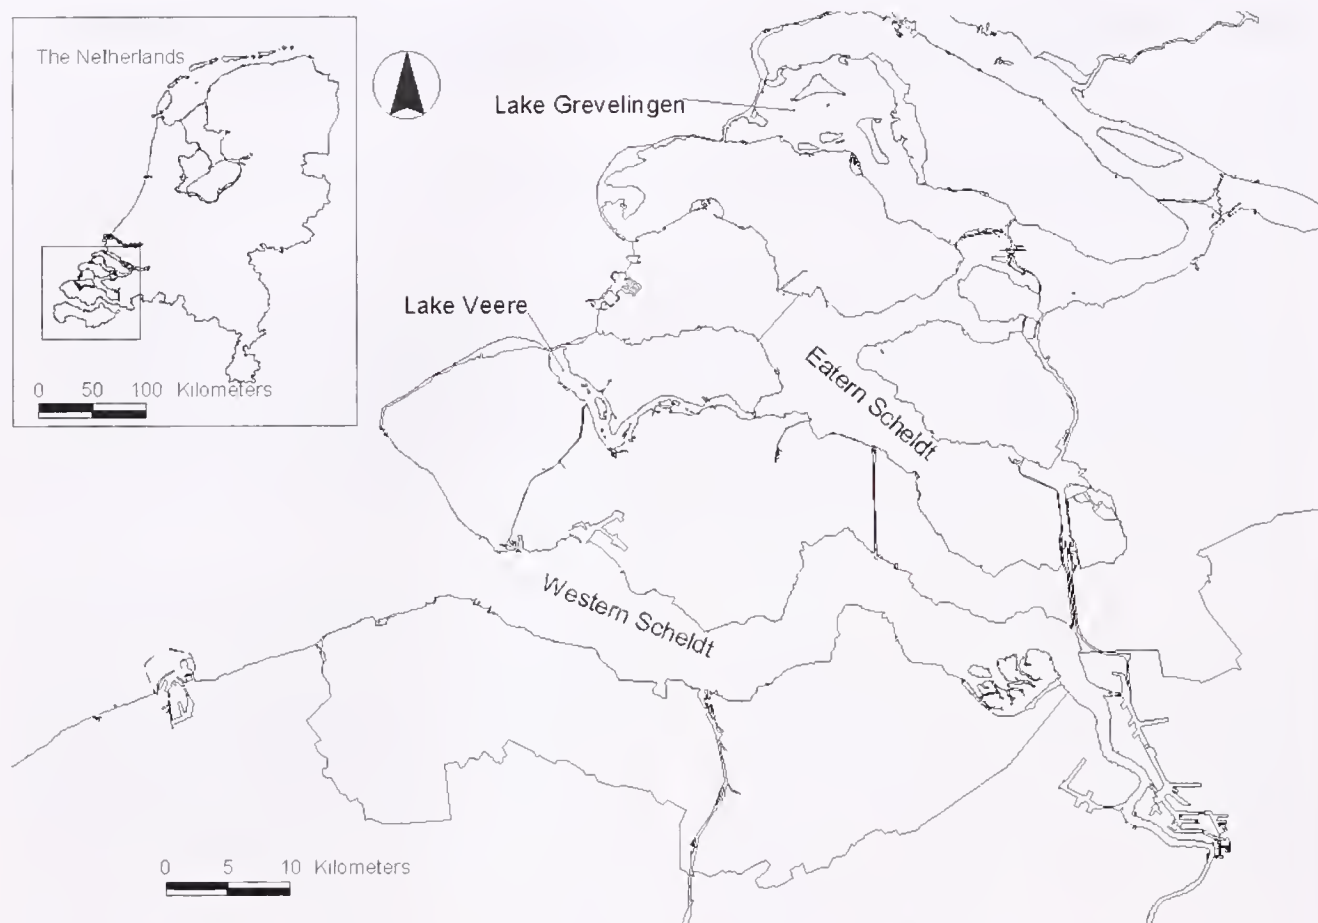

Figure 1. Map of the Netherlands, showing the location of the Eastern Scheldt.

sis. Each photograph was scanned (Microtek Scanmaker 9600 XL). A resolution of 200 dots per inch was used, achieving the desired clarity together with minimal storage space.

All photographs were georeferenced to a map of the Eastern Scheldt, using the extension World File Creator (McVay 1998). Georeferenced photographs were brought into a Geographic Information System (GIS) using ArcView 3.2a.

Oyster beds appear as dark spots on both black & white and false-color photographs. On each photograph oyster beds were located by eye, and within ArcView a polygon was drawn around each bed. The surfaces of each bed were calculated using the extension XTOOLS (DeLaune 2001).

Groundtruth

For verification purposes, oyster bed contours were measured in the field. At low tide, oyster beds lying in an intertidal area fall dry. Contours of these oyster beds were measured by walking around them with a Global Position System (Garmin 12). At each change of direction a waypoint was marked. Waypoints were transferred to ArcView, and waypoints of each oyster bed were connected to form one polygon. Contours were measured in January and February of the years 2000, 2001, and 2002.

Verification Techniques

To compare results obtained with aerial photography, 3 locations were selected based on available information from aerial

photographs and field surveys: Zandkreek, Slikken van Viane, and Stavenisse (Fig. 2).

With the extension XTOOLS (DeLaune 2001) the surface areas of oyster beds, derived from the field survey and aerial photographs of each location, were calculated. These surface areas were used to get an impression of errors introduced by estimating areas from aerial photographs. Two types of errors can be made. First, (parts of) oyster beds seen on an aerial photograph but not found in the field, are called false positives. Second, (parts of) oyster beds not seen on an aerial photograph, but located in the field, are called false negatives.

For further verification purposes, in a GIS a grid of 5 m × 5 m was laid on the intertidal area (i.e., where oysters could be located) of the three chosen locations. To each grid cell the following information was added: (a) are there oyster beds seen during the ground truth present in the grid cell and (b) are there reconstructed oyster beds present in the grid cell. If a grid cell contained both ground truth beds and reconstructed beds, or no ground truth beds and reconstructed beds, it was labeled as correct.

First, the overall accuracy was calculated by dividing the sum of correctly labeled grid cells by the total number of grid cells (Congalton 1991). This is a reasonable way to describe the overall accuracy of a map, but does not account for the component of accuracy resulting from chance alone (Mumby et al. 1997).

Secondly, the user's accuracy (or reliability) was calculated. This measure is indicative of the probability that a grid classified

Figure 2. Map showing areas used for verification purposes.

on the image is actually there on the ground (Story & Congalton 1986). The user's accuracy is calculated by dividing the total number of grid cells that were correctly classified in a category (in this study there are 2 categories: oysters or not-oysters) to the total number of grid cells that were classified in that same category (Congalton 1991).

Finally, a τ coefficient was calculated to give an indication of the number of grid cells classified correctly excluding the correct classification on chance alone (Ma & Redmond 1995). This coefficient is described by:

$$T = \frac{P_0 - P_r}{1 - P_r}, \text{ where } P_r = \frac{1}{N^2} \sum_{i=1}^2 n_i * x_i$$

where

P_0 : overall accuracy

n_i : Total number of grid cells in oyster beds and outside oyster beds

x_i : Total number of correctly classified grid cells in oyster beds and outside oyster beds

N : Total number of grid cells

Construction of an Up-to-Date Oyster Map

To construct an oyster map that describes oyster beds as up to date as possible, all contours measured in 2002 were mapped. Contours measured in 2000 and 2001 were added to this map, but only in areas not described by the 2002 contours. Next, the contours obtained from aerial photographs taken in 1999 and 2000 were added to the map, but only of beds of which no contours were measured. Finally, all areas not described by one of the measured techniques, were described using the reconstruction of 1990. Total surface areas of intertidal oyster beds were estimated using the ArcView extension XTOOLS (DeLaune 2001).

RESULTS

Reconstructions

Aerial photographs taken in 1980 covered about 60% of the intertidal area in the Eastern Scheldt. In particular, areas in the southwestern part are missing. The surface area of oyster beds reconstructed in the photographed area is 15 ha. The total surface area of oyster beds can be estimated by correcting for the areas not

photographed, assuming a homogeneous scattering of oyster beds. The total estimated surface in 1980 is 25 ha.

The year 1990 had the largest coverage of the intertidal area with aerial photographs; photographs cover 89% of the intertidal area in the Eastern Scheldt. Figure 3 shows the results of the reconstruction of oyster beds in 1990. The surface area of reconstructed oyster beds in photographed areas is 210 ha. The corrected estimated surface area is 236 ha.

Available aerial photographs in 1999 and 2000 covered about 40% of the intertidal areas of the Eastern Scheldt.

False Positives and False Negatives

The surface areas of oyster beds found in field surveys and on aerial photographs, and the surface areas of false positives and false negatives, are shown in Table 1. On Stavenisse no false positives (i.e., oyster beds seen on aerial photographs, but not in the field situation) were found. At the other two locations the percentages of false positives were low (2% to 6%). The average percentage of false positives was 2.4%. In all three locations a high percentage of false negatives (no oyster beds seen on aerial photographs, but nonetheless found in the field situation) were found (41% to 59%). The average percentage of false negatives was 53%.

TABLE 1.

Surface areas of oyster beds in field (ha) and on aerial photographs (ha), and surface areas of false positives (ha) and false negatives (ha), for three locations in the Eastern Scheldt.

Location	Field	Photo	False Positive	False Negative
Slikken van Viane	27	17	1.5	11
Zandkreek	73	33	1.6	42
Stavenisse	16	7.0	0	9.5

Accuracy

The overall accuracy, user's accuracy of oysters and tau accuracies of the three selected locations are presented in Table 2. The table shows a high average overall accuracy of 87%, a user's accuracy of 74% and a tau accuracy of 61%.

Oyster Map 2002

The oyster map 2002 is made up of contours measured in 2002, 2001, and 2000, and aerial photographs of 2000 and 1990. Table 3 gives an overview of the contribution of field survey and aerial photography to the 2002 map. The table shows more than 60% of

Figure 3. Reconstruction of oyster beds in 1990.

TABLE 2.
Verification.

	Overall Accuracy	User Accuracy	Tau Accuracy
Zandkreek	84%	60%	58%
Sint Annaland	82%	84%	64%
Viane	94%	77%	62%
Average	87%	74%	61%

the oyster map is based on contours measured in the field. The total surface area of the Eastern Scheldt covered with oyster beds is estimated 640 ha. Figure 4 shows the positions of oyster beds.

DISCUSSION AND CONCLUSIONS

This study describes the usage of aerial photographs to reconstruct the surface areas of intertidal beds of Pacific oysters in the Eastern Scheldt. Using aerial photography for the assessment of

shellfish stocks is not often described. Most studies focus on seagrass beds (e.g., Bulthuis 1995, Pasqualini et al. 1998, Jaubert et al. 1999). Reconstruction of situations in the past has been done before, mostly for seagrass beds. Instead of increasing like oyster beds, seagrass areas tend to decrease in time. Based on aerial photography past situations have been successfully reconstructed for seagrass beds in Australia (Larkum & West 1990, Kendrick et al. 2002) and the USA (Lathrop et al. 2001). From their reconstructions they could conclude an overall decrease in the area of

Figure 4. Oyster map 2002.

Figure 5. Intertidal oyster bed in the Eastern Scheldt.

seagrass beds. An increase of Pacific oyster area can be concluded from the results of this study. Figure 5 shows an example of a large intertidal oyster bed in the Eastern Scheldt.

Field survey is an expensive but necessary aspect of remote sensing. Field data are needed to describe habitats present in an area, identify locations of habitats in the imagery, and to provide an independent evaluation of the thematic accuracy of output maps (Congalton 1991).

Remote sensing products can play an important role in the planning of field studies, particularly when charts or maps are poor (Green et al. 1996). A field study is used to verify results obtained with our aerial photographs.

Frequently, remote sensing studies concerning the inventory and mapping of tropical coastal resources do not include an assessment of accuracy. Of the technical papers reviewed by Green et al. (1996) only 25% presented a quantitative evaluation of the accuracy of the image classification. The accuracy or reliability found in this study (87%) is comparable to the accuracy found by Kristiansen (1997). He estimated the number of occupied Greylag Geese nests using aerial photographs, and visited the nesting site afterwards. Reliability of nest identification from images was found to be 93% correct. Mumby et al. (1997) found user's accuracies for aerial photographs of 76% for coral reefs, 58% for algae, 73% for sand, and 63% for seagrass. In this study oyster beds had a user's accuracy of 74%. Jaubert et al. (1999) used aerial photographs to determine alterations in dimensions of *Posidonia* (seagrass) beds. They used several wavebands to classify several habitats, and concluded that the probability of confusing one subject category with another was extremely small. They did not further quantify the reliability of their work.

This study shows that aerial photography can be an aid in surveying intertidal Pacific oyster beds. Reconstruction of the present situation shows that the chances of false positives (i.e., a spot located as an oyster bed without being an oyster bed, or surface areas being overestimated) are small. On the other hand, in some case more than half of the surface of oyster beds was missed

(false negatives). This can be caused by the fact that the photographs were taken in 1999 and 2000, and the field survey was performed in 2002. A second problem is the tide on the moment photographs were taken. If the tide is not low enough, then several beds can be missed (e.g., Slikken van Viane). This second problem could be tackled by comparing the extent of the exposed intertidal region in the photos with the maps of the beds from 2002. Unfortunately there are no useful reference points on most of the photographs which allow determination whether the tidal elevation at the time the photos were taken obscure any of the beds.

The reconstruction of the present situation shows an underestimation of the surface area of oyster beds, not only due to a time gap between photo and field survey. This means that the chance of an overestimation of the 1980 and 1990 situations are small, but there is a chance that the surface areas for 1980 and 1990 are underestimated. The different accuracies are comparable with accuracies found in other studies.

The technique presented here only covers the inventory of intertidal oyster beds. It's clear there will also be a large surface area of subtidal oyster beds, influencing the intertidal beds in several ways. There are, however, no estimates of these surface areas. It would be very useful to know the extent of the subtidal oyster beds, but it is of course impossible to use aerial photographs. To survey subtidal oysters, techniques like side scan sonar could be useful, but it is beyond the scope of this study to explore the possibilities.

In the maps shown the oyster beds are filled polygons, suggesting areas fully covered with oysters. In the field situation however, not all oysters in the beds are alive. But although dead oyster will not compete for food with other shellfish, they still occupy space and prevent settling of cockles and oysters (Smaal et al. 2001). For biomass estimation, aerial photographs cannot be used and field survey is still necessary.

In conclusion, digital photographs can be helpful in (re)constructing intertidal oyster bed maps. The years of 1980, 1990, and 2002 were mapped, and the development of intertidal oyster beds in the Eastern Scheldt can be shown. To make useful aerial photographs for the determination of surface areas of oyster bed, low tide and good clear weather are essential. In some cases the aerial photographs were malfunctioned after scanning or rotating. It is recommended to use digital, georeferated photographs in future.

This method has the potential to be helpful in estimating the size of surface areas of intertidal Pacific oyster beds. It could reduce the need for relatively intensive field surveys.

ACKNOWLEDGMENTS

The authors thank Jack Perdon and the crew of the Schollevaar for assistance in the field, Joris Geurts van Kessel and Annemieke van der Pluim (RIKZ) for making the aerial photographs of the Eastern Scheldt disposable, Pauline Kamermans and Karin Troost for improving the manuscript by critical comments, and John McDarby for improving the English.

GROWTH AND SURVIVORSHIP OF NON-NATIVE (*CRASSOSTREA GIGAS* AND *CRASSOSTREA ARIAKENSIS*) VERSUS NATIVE EASTERN OYSTERS (*CRASSOSTREA VIRGINICA*)

JONATHAN H. GRABOWSKI,* CHARLES H. PETERSON, SEAN P. POWERS,
DAVID GASKILL AND HENRY C. SUMMERSON

University of North Carolina at Chapel Hill, Institute of Marine Sciences,
Morehead City, North Carolina 28557

ABSTRACT The decline of wild populations of the eastern oyster *Crassostrea virginica* from fishing impacts and disease combined with limited success in its culture has stimulated discussion among coastal managers about the risks and benefits of introducing non-native oysters in Maryland, Virginia, and North Carolina. Field experiments in 1999 to 2000 and 2001 to 2002 comparing growth, survivorship, and prevalence of disease in 2 non-native oysters, *C. gigas* and *C. ariakensis*, versus *C. virginica* in North Carolina estuaries demonstrated that in high-salinity (>25‰) waters, performance of *C. gigas* in culture greatly surpassed that of both of the other oysters (with growth 162.4% higher than *C. virginica* and 54.1% higher than *C. ariakensis* and survivorship 33.1% higher than *C. virginica* and 22.3% higher than *C. ariakensis*). *C. ariakensis* survivorship at these high salinity sites was highly variable and unpredictable even when using environmental covariates, and at salinities below ~10‰ this species did not grow, rendering its culture nonviable at low salinity. However, in waters of intermediate salinity (15‰ to 25‰), *C. ariakensis* outgrew both of the other 2 oysters (35.9% higher than *C. gigas* and 24.5% higher than *C. virginica*) and exhibited 42.1% higher survivorship than *C. gigas*. Although survivorship of *C. virginica* and *C. ariakensis* did not differ significantly at intermediate salinities, only *C. virginica* failed to achieve legally harvestable sizes and, based on its increasingly high susceptibility to death from disease with age, is likely to have experienced much greater mortality by the time of complete grow-out. Experimental elevation above the bottom augmented growth and survivorship of *C. ariakensis* most strongly, whereas *C. gigas* was not influenced by rack height. Before large-scale introduction of any non-native oyster occurs, the quantitative biologic results should first be incorporated into economic evaluations that weigh expected profitability and ecosystem benefits against the potential ecologic risks of introduction (both for wild release and for aquaculture of triploids).

KEY WORDS: *Crassostrea ariakensis*, *Crassostrea gigas*, *Crassostrea virginica*, economic feasibility, triploid, oyster disease, oyster growth, oyster survivorship

INTRODUCTION

Previous introductions of non-native species have often had severe consequences for ecologic communities, including reduction of the diversity, abundance and distribution of native fauna and flora (Carlton 1992, Ruiz et al. 2000). Consequently, prior to intentionally introducing any exotic fisheries species, managers should carefully weigh potential negative against positive ecological effects and evaluate under what conditions (aquaculture of nonreproductives versus wild release), if any, introduction may be economically and ecologically justifiable. A key component of this evaluation process is defining the rationale or need for introduction (Carriker 1992). Specifically, there must be clearly identified and scientifically defensible reasons why the native species is inadequate (Courtney & Robins 1989) and the introduced species is expected to have a high potential for success (Mann 1979, Rosenfield & Kern 1979, Mann et al. 1991).

Frustration with the slow pace of restoration efforts targeting wild populations of the eastern oyster *Crassostrea virginica* (Gmelin 1791) coupled with high mortality rates associated with culture of this species over the past several decades have resulted in advocacy by the shellfish industry to introduce non-native oysters in Maryland, Virginia, and North Carolina (Mann et al. 1991, Byrne 1996, Shatkin et al. 1997). Two species, the Pacific oyster, *C. gigas* (Thunberg 1793), and the Suminoe oyster, *C. ariakensis* (Fujita 1913), have been proposed as candidates for triploid aquaculture and even wild introductions. Native to Japan and the Korean peninsula (Mann et al. 1991), *C. gigas* has been successfully introduced to France, Oregon, Washington, western Canada, Australia, and New Zealand (Shatkin et al. 1997) and currently ac-

counts for over 80% of the world's fishery production of oysters (Ayers 1991). Despite some taxonomic confusion with *C. rivularis*, the native distribution of *C. ariakensis* is believed to range from Pakistan through China to Japan, where it extends well into lower-salinity (i.e., <25‰) portions of estuaries (Breese & Malouf 1977, Langdon & Robinson 1996).

Resource managers currently face one of the most ecologically critical decisions in the history of environmental and fisheries management in the United States, whether *C. gigas* or *C. ariakensis* should be either intentionally released to propagate in the wild or cultured as nonreproductives in controlled aquaculture settings (National Research Council 2003). Some past studies provide information on and discussions of potential ecologic risks and perceived ecosystem (e.g., enhanced bio-filtration rates) and fisheries benefits of the 2 types of introduction (Mann 1979, Andrews 1980, Mann et al. 1991, Gaffney & Allen 1992, Lipton et al. 1992, Byrne 1996, Gottlieb & Schweighofer 1996, Shatkin et al. 1997). Several scientists have emphasized that significant risks to local and regional ecosystems exist and have yet to be fully addressed. For instance, introduction of reproductively viable non-native oysters could lead to eventual invasion of other estuaries in neighboring states or regions of the United States. Because information on the biology of these 2 species is sparse, the NRC Committee on Non-native Oysters in the Chesapeake Bay recently recommended that further research be conducted on the performance of native versus non-native oyster species (National Research Council 2003).

Realization of the potential fisheries benefits of introducing non-native oysters depends on their biology within the estuaries of the eastern United States, their marketability (see Grabowski et al. 2003 for relevant comparative information on marketability), and the integrated bioeconomics. Previous studies performed in Ches-

*Corresponding author. E-mail: jgrabowski@gmri.org

peake Bay comparing the biology of *C. virginica* to either *C. ariakensis* or to *C. gigas* (Barber & Mann 1994, Calvo et al. 1999, Calvo et al. 2001) have documented higher resistance to *Perkinsus marinus* and *Haplosporidium nelsoni* and faster individual growth rates of both non-native species compared with *C. virginica* (Langdon & Robinson 1996, Calvo et al. 1999, Calvo et al. 2001), although the growth advantage seems to vary with salinity for *C. gigas*. However, direct comparison of the two non-native oyster species has yet to be conducted within the eastern United States and neither non-native species has been experimentally cultured in North Carolina. Here we present results of field trials covering the full range of potentially viable salinity regimes in coastal North Carolina. These trials were designed to assess the growth, survivorship, and disease prevalence and severity of the two non-native species under consideration for introduction and contrast these results to those obtained simultaneously for *C. virginica*. In addition, we tested if elevating oysters off the bottom differentially affects survival and growth of native versus non-native oysters.

MATERIALS AND METHODS

A series of experiments was conducted to compare growth, survivorship, and disease (dermo, *P. marinus*) prevalence and severity among native *C. virginica* (eastern oyster) and 2 non-native species, *C. gigas* (Pacific oyster) and *C. ariakensis* (Suminoe oyster), in North Carolina from 1999 to 2002. For each experiment, triploid seed *C. gigas* and *C. ariakensis* were obtained from the quarantine hatchery at the Virginia Institute of Marine Sciences (VIMS) and compared with diploid *C. virginica* obtained from Leslie Lee, Sloop Point Seafood, Hampstead, North Carolina. Triploid non-native oysters were raised at VIMS until achieving approximately 2–6 cm shell height (SH) in size, and tested for ploidy and disease status. Disease-free triploid oysters were shipped to the University of North Carolina-Institute of Marine Sciences (UNC-IMS), where they were held in upwellers prior to initiating field trials. Native oysters were raised at Sloop Point Seafood in raceways until the inception of each experimental trial. Oysters were then cultured in 4.8-mm mesh polyethylene bags that were elevated above the bottom using racks constructed from iron bars and located at approximately 0.1–0.5 m below mean low water (MLW) in research sanctuaries throughout coastal North Carolina.

First Series of Experiments (1999–2000)

Grow-out experiments were performed in 1999 to 2000 to compare growth and survivorship of *C. virginica* versus *C. ariakensis* and *C. virginica* versus *C. gigas* in separate experiments. In December 1999, *C. ariakensis* (mean SH \pm 1 SE = 54.8 \pm 0.9 mm) and *C. virginica* (42.6 \pm 1.0 mm) were placed in 4.8-mm polyethylene (43 \times 48 \times 4 cm) bags on 15 cm-high racks at 1 high-salinity site (>25‰; Chadwick Bay) and 1 site with low (<10‰; Broad Creek) salinity (Fig. 1, Table 1). Abnormal environmental conditions following Hurricane Floyd resulted in extremely low salinity levels at Broad Creek in 2000 (Peterson 2000). Three bags of each species were deployed at each site with 52 oysters per bag. Living oysters were subsequently measured (SH) and counted to assess size and survivorship in March, June, and September/October 2000 at both sites.

C. gigas (31.4 \pm 0.8 mm) and *C. virginica* (29.5 \pm 0.6 mm) were placed in 6 polyethylene bags (50 oysters per bag, 3 bags per species) and deployed in February 2000 on 15 cm-high racks at

each of 2 high-salinity sites in Waters Bay and Chadwick Bay (see Fig. 1). Deployment time for *C. gigas* differed from that of *C. ariakensis* described earlier because of availability of hatchery seed. *C. gigas* was not planted at Broad Creek because its poor performance at low salinities is already well documented (Calvo et al. 1999). Living oysters for the *C. virginica*/*C. gigas* contrast were subsequently measured (SH) and counted in May and August 2000 at both sites. For both the *C. virginica*/*C. ariakensis* and *C. virginica*/*C. gigas* experiments, oyster bags were washed with pressurized water and scrubbed with wire brushes to remove accumulated mud and fouling organisms during each sampling visit.

Second Series of Experiments (2001–2002)

The second series of experiments was initiated in April 2001 and included comparisons of growth, survivorship, *P. marinus* infection and *Polydora* spp. infestation among *C. ariakensis*, *C. gigas*, and *C. virginica*. Three bags of 70 *C. ariakensis* (31.8 \pm 1.0 mm) and 3 bags of 70 *C. virginica* (20.6 \pm 0.3 mm) were placed at each of 4 high-salinity (>25‰; Topsail Sound, Waters Bay, Chadwick Bay and Newport River, see Fig. 1) and 3 intermediate-salinity (15‰ to 25‰; Bay River, Broad Creek and Swan Quarter) sites. In addition, 3 bags of 70 *C. gigas* (18.7 \pm 0.3 mm) were placed at each of the high- and 1 intermediate-salinity (Bay River) sites to determine if slightly reduced salinities negatively impact *C. gigas* growth and survivorship in North Carolina. Bags (4.8-mm mesh, 43 \times 48 \times 4 cm) containing each set of seed oysters were placed on 15 cm-high rebar racks 0.1–0.5 m below MLW. To determine if height above the bottom affects native or non-native oyster growth and survivorship, 3 bags of *C. virginica*, 3 bags of *C. gigas*, and 3 bags of *C. ariakensis* were planted on racks at each of 2 additional heights (on the seabed and 38 cm above the seabed) at 2 sites (Chadwick Bay and Newport River).

Living oysters at high salinities were subsequently measured (SH) and counted in June, October, and November 2001. Living oysters at intermediate salinities were measured (SH) in June and October 2001, and February 2002. Salinity (‰), dissolved oxygen (mg/L), and water temperature (°C) at 0–25 cm beneath the water surface were measured monthly at each site from May to August 2001 during the experiment. Bags were cleaned with pressurized water and brushes monthly during the summer and seasonally during the fall and winter.

At each site, up to 24 oysters (4–8 oysters from each bag per species) were tested in August and October 2001 for prevalence and intensity of the oyster disease *P. marinus* and shell infestation rates by the mud worm *Polydora* spp. When testing for *P. marinus* infections, a 3–5-mm-long section of the rectum was removed from each oyster and analyzed for the presence and intensity of *P. marinus* using Ray's fluid Thioglycollate medium (RTFM) assays (Ray 1952, Ray 1963, Paynter & Burrenson 1991). Infection intensity was calculated using the method described by Ray (1954) and Mackin (1962), with infection intensity categorized into the following groups: (0) absent, (1) light, (3) moderate, (5) heavy (Calvo et al. 1999, Lenihan et al. 1999). Average weighted intensity of *P. marinus* then was calculated for each species at each site by multiplying the number of oysters with each infection level by its infection intensity and dividing this sum by the total number of oysters tested. Intensity of *Polydora* spp. shell infestation was rated on a scale of 0 to 4 to describe the approximate percentage of the external oyster shell (right valve only) covered by mud worm tubes ([0] absent, [1] <25%, [2] 25% to 50%, [3] 50% to

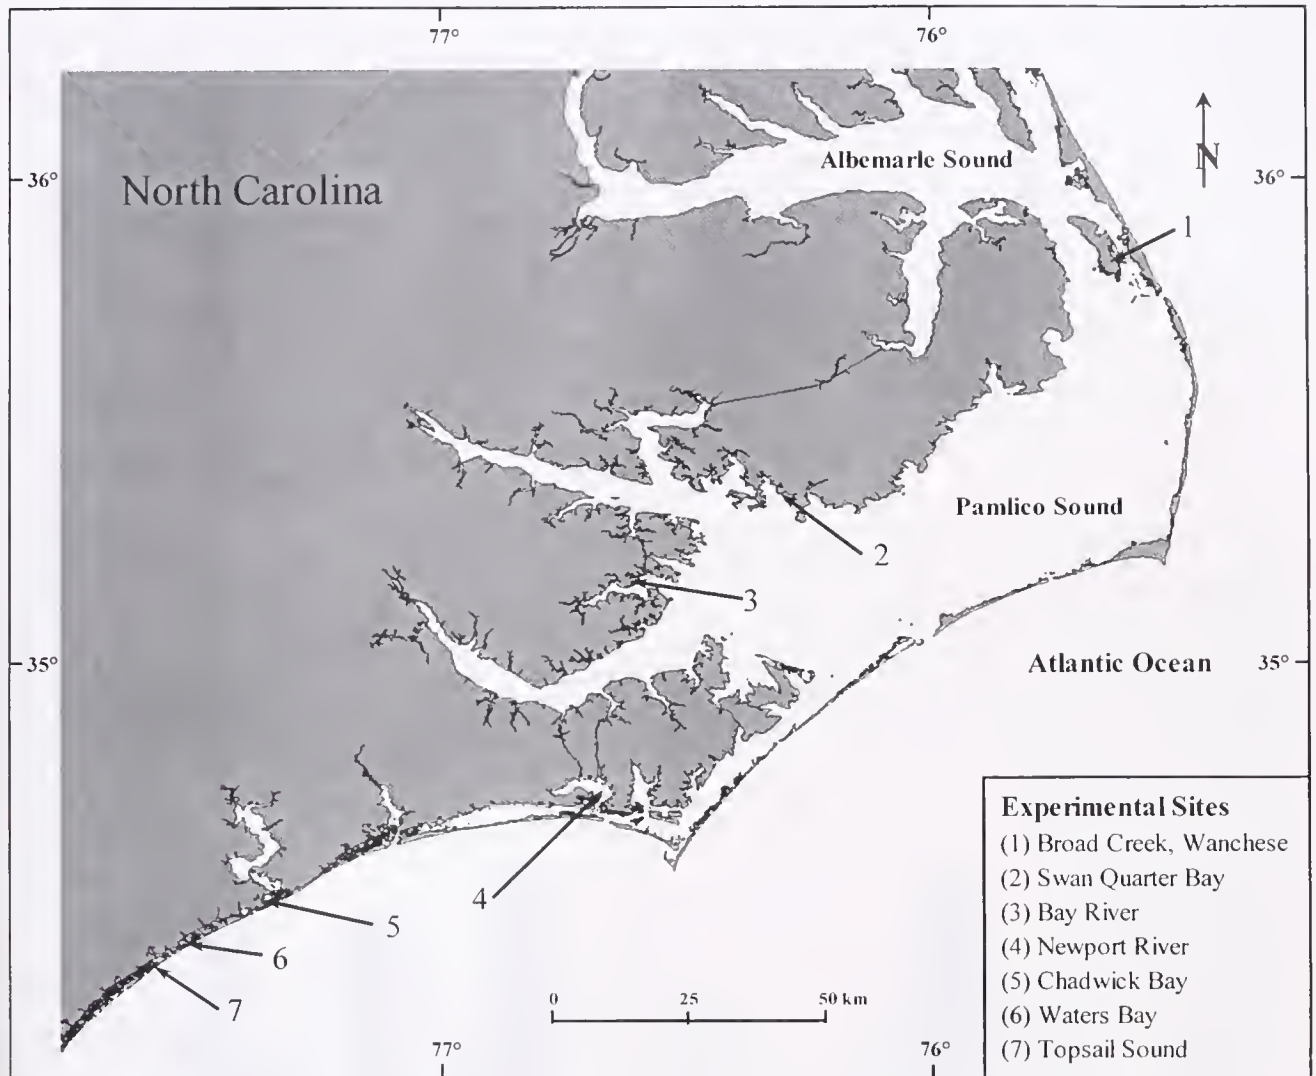

Figure 1. Location of experimental sites where native and non-native oysters were cultivated in 1999 to 2000 and 2001 to 2002 in coastal North Carolina, USA.

75%, and [4] >75% coverage). Weighted intensity was calculated by multiplying the number of oysters with each intensity level by their respective infestation intensity and dividing the sum by the total number of oysters tested.

Statistical Analyses

A series of multifactor ANOVAs was performed to test if growth and survivorship varied between or among oyster species

TABLE 1.

and whether these patterns were modified by grow-out site. Cochran's test for homogeneity of variances was conducted on all main effects prior to each analysis (Underwood 1981). For datasets that violated this assumption at α of 0.05, fourth-root transformations were performed and transformed data were tested. For experiments conducted in 1999 and 2000, separate 2-way ANOVAs were performed on oyster growth (final SH minus initial SH) and survivorship with site (Chadwick Bay and Broad Creek) and species (*C. ariakensis* and *C. virginica*) as fixed factors. A second set of separate 2-way ANOVAs was performed on oyster growth and survivorship with site (Chadwick Bay and Waters Bay) and species (*C. gigas* and *C. virginica*) as fixed factors. For experiments initiated in 2001, we conducted a series of analyses to compare growth and survivorship of the 3 oyster species within each salinity regimen. At relatively high salinities, we analyzed the effects of site (Chadwick Bay, Newport River, Topsail Sound, and Waters Bay) and species (*C. ariakensis*, *C. gigas*, and *C. virginica*) on growth and survivorship using separate 2-way ANOVAs with fixed factors. The effect of species (*C. ariakensis*, *C. gigas*, and *C. virginica*) on oyster growth and survivorship at Bay River (intermediate salinity) was analyzed using separate 1-way (fixed factor) ANOVAs. For the other 2 intermediate-salinity sites, 2-way ANOVAs were conducted on growth and survivorship with site (Swan Quarter Bay and Broad Creek) and species (*C. ariakensis* and *C. virginica*) as fixed factors. To test the effect of elevating oysters on their growth and survivorship, a 3-way ANOVA was

performed with site (Chadwick Bay and Newport River), species (*C. ariakensis*, *C. gigas*, and *C. virginica*), and elevation (bottom, low, and high) as fixed factors. Student-Newman-Keuls (SNK) *post hoc* tests at α of 0.05 were conducted on all main effects. If an interaction proved significant in 2-way ANOVAs, SNK tests were performed among treatments within each level of a factor. The SNK test was selected because we conducted a balanced experiment with *a priori* predictions and fixed factors (Day & Quinn 1989).

RESULTS

First Series of Experiments

Results of the contrasts between *C. ariakensis* and *C. virginica* varied between the (low-salinity) Broad Creek and (high-salinity) Chadwick's Bay sites. *C. ariakensis* deployed in December grew by September from 55.3 mm SH to 56.9 ± 0.6 mm (mean \pm 1 standard error) at Broad Creek and from 54.3 to 99.3 ± 1.9 mm at Chadwick Bay, while *C. virginica* increased during this period from 42.5 to 51.0 ± 2.2 mm at Broad Creek and from 42.6 to 71.0 ± 0.9 mm at Chadwick Bay. ANOVA revealed a significant effect of the interaction between site and species ($F_{1,8} = 79.1$, $P < 0.0001$; Fig. 2a) on oyster growth (i.e., change in shell height). *C. ariakensis* grew 16.6 mm more than *C. virginica* at the high-salinity Chadwick Bay, but *C. virginica* outgrew *C. ariakensis* by 6.8 mm at the low-salinity Broad Creek (SNK *post hoc* compari-

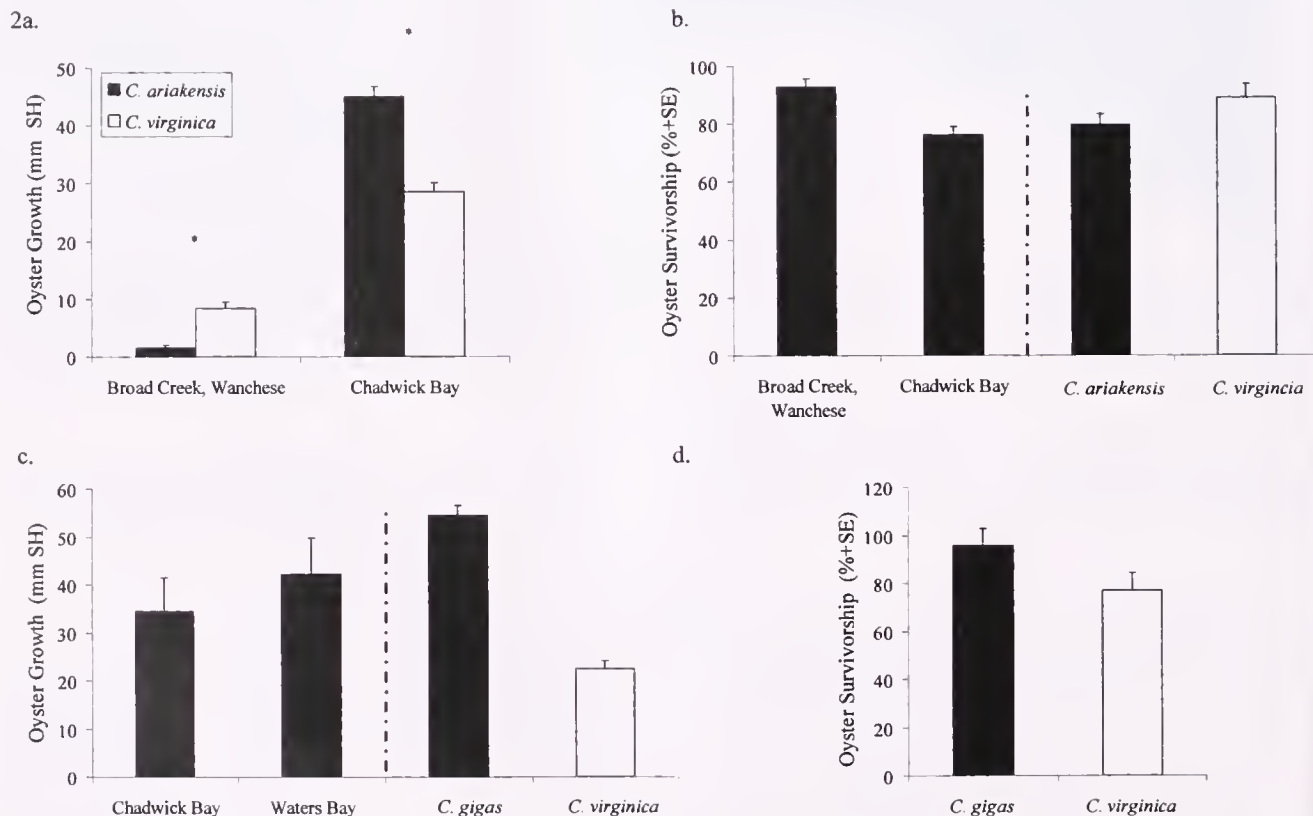

Figure 2. (a) *C. ariakensis* and *C. virginica* growth (final SH to initial SH) from December 1999 to September 2000 at Broad Creek and Chadwick Bay sites (+SE; $n = 3$). Significance levels (* $P < 0.05$; ns $P > 0.05$) presented above bars are from SNK *post hoc* tests conducted to explore the cause of the significant species \times site interaction. (b) Oyster (both *C. ariakensis* and *C. virginica*) survivorship at each of the 2 sites and survivorship of *C. ariakensis* versus *C. virginica* after 9 mo of culture (+SE; $n = 6$). (c) Oyster (both *C. gigas* and *C. virginica*) growth at Chadwick Bay versus Waters Bay and *C. gigas* versus *C. virginica* growth from February to August in 2000 (+SE; $n = 6$). (d) *C. gigas* versus *C. virginica* survivorship after 7 mo of oyster culture at Chadwick Bay and Waters Bay (+SE; $n = 6$).

sons; see Fig. 2a). ANOVA revealed that the interaction between site and species did not affect oyster survivorship ($F_{1,8} = 0.3$, $P = 0.58$). Oyster survivorship at Chadwick Bay was 16.5% higher than at Broad Creek (site effect: $F_{1,8} = 28.4$, $P = 0.0007$), and survivorship of *C. virginica* was 9.4% higher than that of *C. ariakensis* (species effect: $F_{1,8} = 9.1$, $P = 0.02$; see Fig. 2b).

Results of the contrasts between *C. gigas* and *C. virginica* did not vary between sites, both of which had similarly high salinities. By the end of August 2000, *C. gigas* deployed in January 2000 grew from 31.3 to 81.3 ± 1.1 mm SH at Chadwick Bay and from 31.5 to 90.2 ± 2.1 mm at Waters Bay, whereas *C. virginica* grew from 29.8 to 48.8 ± 1.7 mm at Chadwick Bay and from 29.1 to 54.8 ± 1.7 mm at Waters Bay. For the contrast between *C. gigas* and *C. virginica*, ANOVA revealed no significant effect of the interaction between site and species on either growth ($F_{1,8} = 0.4$, $P = 0.56$) or survivorship ($F_{1,8} = 0.4$, $P = 0.53$). *C. gigas* grew more than *C. virginica* at both sites (species effect: $F_{1,8} = 455.3$, $P < 0.0001$), and oyster growth was higher at Waters Bay for both species (site effect: $F_{1,8} = 26.6$, $P = 0.0009$; see Fig. 2c). Survivorship of *C. gigas* was 18.7% higher than that of *C. virginica* across both sites (species effect: $F_{1,8} = 8.8$, $P = 0.02$; see Fig. 2d). Thus, in these high-salinity sites *C. gigas* grew faster and survived better than the native oyster.

Second Series of Experiments

Salinity, Temperature, and Dissolved Oxygen

Physical parameters were quantified in the summer of 2001 to indicate how variation in these factors might influence patterns of

oyster growth and mortality. Between May and August 2001, mean salinity was 38‰ at Chadwick Bay, Waters Bay, and Topsail Sound and 34‰ at Newport River sites (Table 1). Mean dissolved oxygen ranged from 5.4 to 6.6 mg/L and mean water temperature from 24.0°C to 26.8°C during this period at the high-salinity sites (Table 1). Between May and August 2001, mean salinity was 18‰, dissolved oxygen 5.5 mg/L, and water temperature 26.7°C at Bay River (Table 1). Mean salinity at Swan Quarter Bay (16‰) was slightly lower than at Broad Creek (18‰) between May and August 2001 (Table 1). Mean dissolved oxygen was higher than all other sites at Swan Quarter Bay (7.2 mg/L), and this was the only site for the entire study where relatively low (<4.5 mg/L) dissolved oxygen levels were never recorded (Table 1). Finally, mean water temperature was slightly higher at Swan Quarter Bay (28.6°C) than at Broad Creek (27.1°C; Table 1).

High-salinity Sites

C. ariakensis versus *C. gigas* versus *C. virginica*. Growth and survivorship differed among non-native and native oysters in this set of trials. From April to November 2001, *C. gigas* in high salinity grew from 19.2 to 101.4 ± 2.3 mm SH (means of all 4 sites), *C. ariakensis* from 31.6 to 86.0 ± 2.2 mm, and *C. virginica* from 20.7 to 52.4 ± 1.9 mm. The interaction between site and species did not affect oyster growth ($F_{6,24} = 2.0$, $P = 0.11$), but each main effect was significant (site: $F_{3,6} = 25.8$, $P < 0.0001$; species: $F_{2,6} = 346.3$, $P < 0.0001$). Oyster growth at Waters Bay was greater than all other sites, which did not differ (SNK *post hoc* comparisons; Fig. 3a). *C. gigas* growth was greater

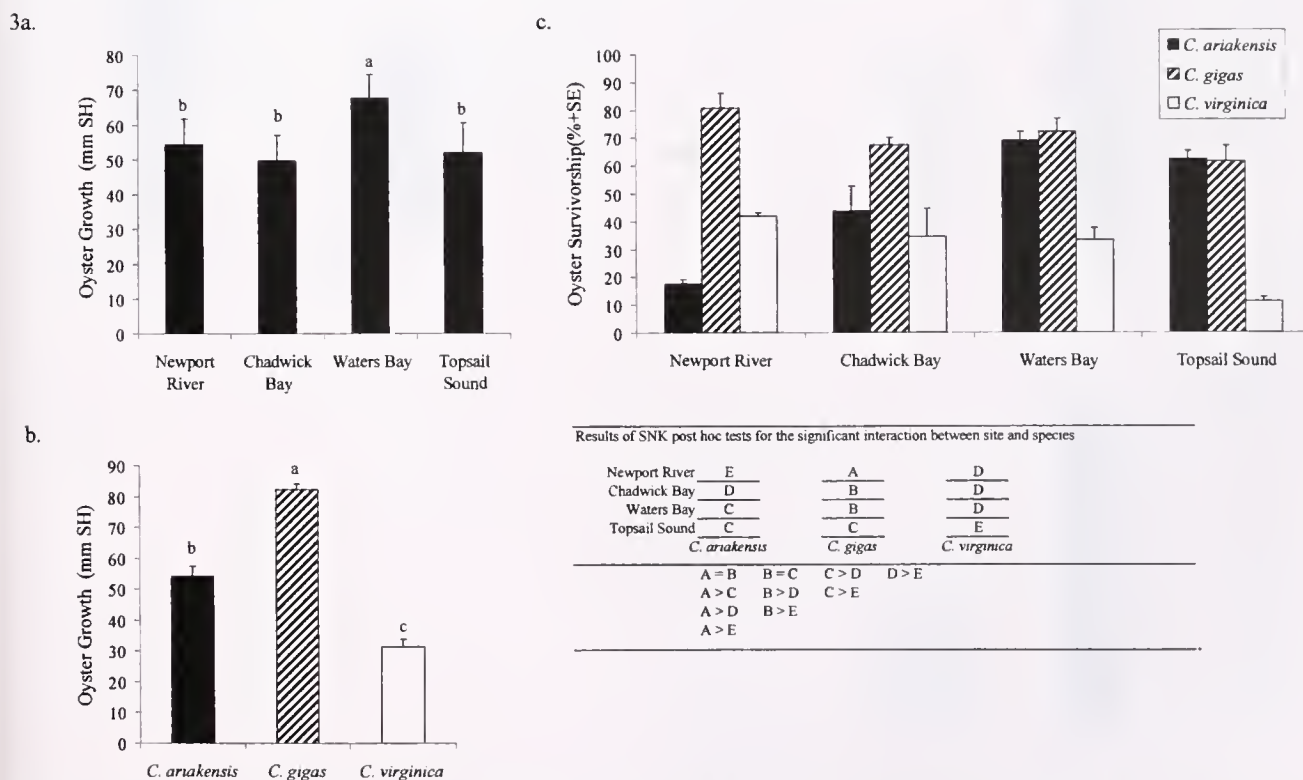

Figure 3. Culture of all 3 species at sites with high salinities from April to November in 2001. (a) The effect of site on oyster growth (final SH to initial SH) of all 3 species combined after 7 mo of culture (+SE; $n = 9$). Sites with different letters above error bars are significantly different at $P < 0.05$ (SNK *post hoc* tests). (b) The effect of species on growth of each species during oyster culture (+SE; $n = 12$). (c) The interaction between site and species on oyster survivorship at high salinities (+SE; $n = 3$).

than that of the other 2 species, and *C. ariakensis* outgrew *C. virginica* (see Fig. 3b). ANOVA revealed a significant interaction of site and species for oyster survivorship ($F_{6,24} = 12.8$, $P < 0.0001$; see Fig. 3c). Survivorship of *C. gigas* exceeded that of *C. ariakensis* at the Chadwick Bay and Newport River sites, and was greater than that of *C. virginica* at all 4 sites (Fig. 3c). Survivorship of *C. ariakensis* exceeded that of *C. virginica* at Topsail Sound and Waters Bay, but was less than that of *C. virginica* at Newport River (Fig. 3c). Finally, survivorship of *C. ariakensis* and *C. virginica* did not differ at Chadwick Bay (Fig. 3c).

Intermediate-salinity Sites

Bay River (*C. ariakensis* versus *C. gigas* versus *C. virginica*). In contrast to the results at the high-salinity sites, both *C. ariakensis* and *C. virginica* exhibited higher growth and survivorship than *C. gigas* at Bay River. From April 2001 to February 2002, *C. ariakensis* had grown from 32.5 to 82.9 ± 1.7 mm SH. *C. virginica* from 20.1 to 56.3 ± 0.02 mm, and *C. gigas* from 16.5 to 43.2 ± 1.1 mm. *C. ariakensis* outgrew both of the other species, and growth of *C. virginica* was greater than that of *C. gigas* (SNK *post hoc*

comparisons; $F_{2,6} = 88.0$, $P < 0.0001$; Fig. 4a). Survivorship did not differ between *C. ariakensis* and *C. virginica*, but survivorship of each was greater than that of *C. gigas* ($F_{2,6} = 52.4$, $P = 0.0002$; see Fig. 4b).

Broad Creek and Swan Quarter Bay (*C. ariakensis* versus *C. virginica*). The pattern exhibited at the other intermediate-salinity site (Bay River) of higher growth of *C. ariakensis* than *C. virginica* but equivalent survivorship was replicated in this set of trials. From April 2001 to February 2002, *C. ariakensis* grew from 31.4 to 62.1 ± 1.0 mm SH at Broad Creek and from 31.1 to 80.7 ± 3.5 mm at Swan Quarter Bay, whereas *C. virginica* increased from 18.8 to 48.8 ± 1.0 at Broad Creek and from 18.9 to 56.5 ± 0.6 mm, respectively, at the 2 sites. ANOVA revealed a significant effect of the interaction between site and species for oyster growth ($F_{1,8} = 7.5$, $P = 0.03$; Fig. 4c). *C. ariakensis* outgrew *C. virginica* at Swan Quarter Bay, but not at Broad Creek (SNK *post hoc* comparisons; Fig. 4c). For both species, growth was greater at Swan Quarter Bay than at Broad Creek (Fig. 4c). ANOVA revealed no significant effect on oyster survivorship of either main effect (site: $F_{1,8} = 0.5$, $P = 0.51$; species: $F_{1,8} = 1.4$, $P = 0.27$) or the interaction between site and species ($F_{1,8} = 2.8$, $P = 0.13$). Mean survivor-

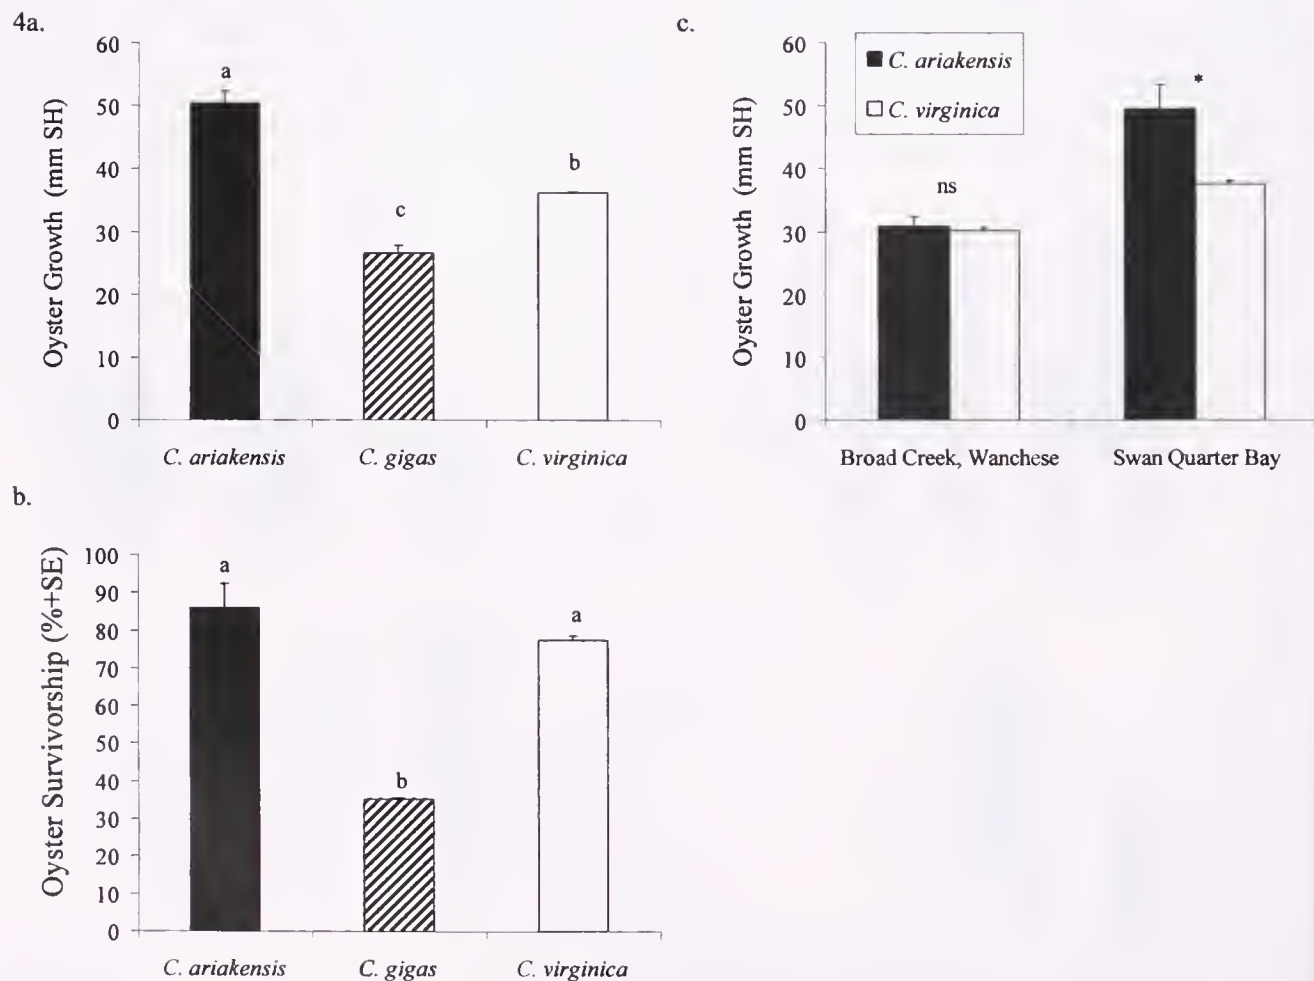

Figure 4. Oyster culture at intermediate-salinity sites from April 2001 to February 2002. (a) Growth and (b) Survivorship of all 3 species at Bay River from April 2001 to February 2002 (+SE; $n = 3$ for both graphs). Species with different letters above error bars are significantly different at $P < 0.05$. (c) *C. ariakensis* and *C. virginica* growth at Broad Creek and Swan Quarter Bay from April 2001 to February 2002 (+SE; $n = 3$). Significance levels (* $P < 0.05$; ns $P > 0.05$) presented above bars are from SNK *post hoc* tests conducted to explore the cause of the significant site X species interaction.

ship at these 2 sites was 74.1 ± 4.2 for *C. ariakensis* and 83.4 ± 7.3 for *C. virginica*.

Oyster Elevation Experiment

C. ariakensis versus *C. gigas* versus *C. virginica*. Elevating oysters enhanced the growth of *C. ariakensis* more than that of the other two oyster species. ANOVA revealed a significant effect of the 3-way interaction among site, species, and elevation for oyster growth (Table 2 and Fig. 5a). Height of oysters did not affect *C. gigas* growth at either site (SNK *post hoc* comparisons: Table 2,

Table 3 and Fig. 5a). *C. ariakensis* growth was greater on high racks than on the bottom at both sites, and was also greater on high-rack racks than on low racks at Chadwick Bay (Table 2, Table 3, and Fig. 5a). *C. virginica* growth was greatest on high racks, intermediate on low racks, and lowest on the bottom at Newport River, but did not differ at Chadwick Bay (Table 2, see Fig. 5a). *C. gigas* growth was greater than that of the other 2 species for all 3 elevations at both sites (Table 2, Table 3, and Fig. 5a). *C. ariakensis* growth was greater than that of *C. virginica* at all 3 elevations at both sites except for the bottom at Chadwick Bay, where the 2 species did not differ (see Table 2 and Fig. 5a).

TABLE 2.

The effect of site (Newport River and Chadwick Bay), species (*C. ariakensis*, *C. gigas*, and *C. virginica*), and elevation (bottom, low rack, and high rack) on oyster growth (change in shell height: SH) and survivorship in 2001 analyzed using separate 3-way ANOVAs.

	Oyster Growth (SH)					Oyster Survivorship

Notes: Provided also are results of SNK *post hoc* tests (using Bonferroni's adjustment for multiple contrasts to maintain experiment-wise $\alpha = 0.05$) for each significant interaction at $P < 0.05$ for the above analyses.

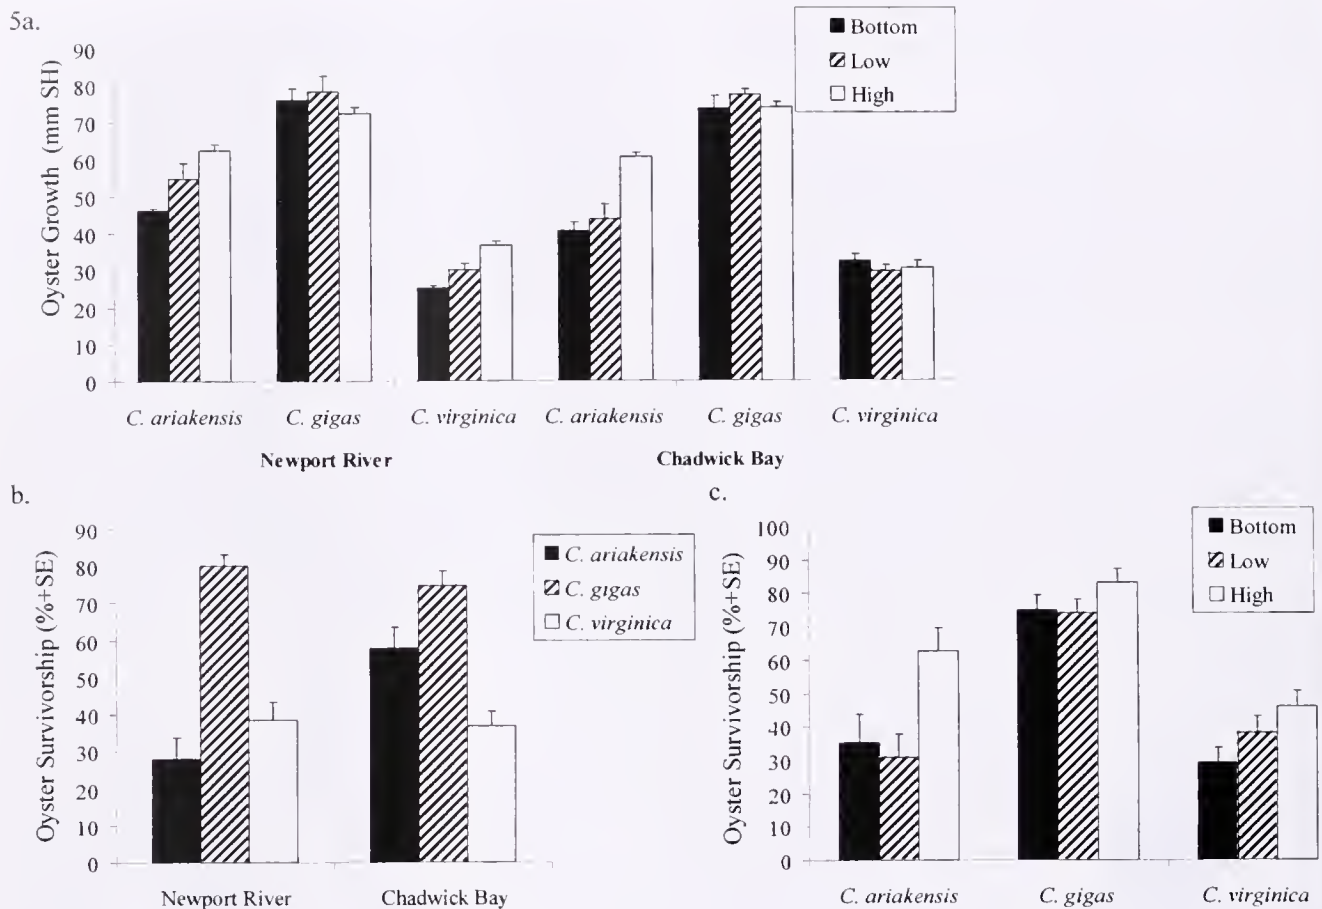

Figure 5. Culture of all 3 species on racks of differing elevations and on the bottom from April to November of 2001 at Newport River and Chadwick Bay. (a) The three-way interaction among site, species and elevation on oyster growth (+SE; $n = 3$). (b) The two-way interaction between site and species on oyster survivorship (+SE; $n = 9$). (c) The two-way interaction between species and elevation on oyster survivorship (+SE; $n = 6$). See Table 2 for results of SNK *post hoc* tests for each of the 3 graphs.

Although ANOVA of oyster survivorship revealed no 3-way interaction among site, species and elevation, all 3 2-way interactions were significant (site X species, species X elevation) or marginally significant (site X elevation; Table 2 and Fig. 5b,c). For the interaction between site and species, *C. gigas* survivorship was significantly higher than that of the other 2 species at both sites (SNK *post hoc* comparisons; Table 2 and Fig. 5b). *C. ariakensis* survivorship was greater than that of *C. virginica* at Chadwick Bay, but survivorship of the 2 species did not differ at Newport

River (Table 2 and Fig. 5b). For the interaction between species and elevation, elevating oysters did not affect survivorship of *C. gigas* (Table 2 and Fig. 5c). In contrast, elevating *C. ariakensis* from the bottom or low racks to high racks increased its survivorship (Table 2 and Fig. 5c). Survivorship of *C. virginica* was greater on high racks than on the bottom, but did not differ from low racks (Table 2 and Fig. 5c). *C. gigas* survivorship was greater than that of the other 2 species at all 3 elevations (Table 2 and Fig. 5c). Survivorship was greater for *C. ariakensis* than for *C. virginica*

TABLE 3.

Initial and final oyster sizes (shell height) of oysters grown at each elevation (bottom, low rack, and high rack) from April to November of 2001 at high-salinity sites (Newport River and Chadwick Bay) in North Carolina.

Site	Elevation	<i>C. ariakensis</i>		<i>C. gigas</i>		<i>C. virginica</i>	
		Initial SH	Final SH	Initial SH	Final SH	Initial SH	Final SH
Newport River	Bottom	30.4	76.8 (0.6)	20.9	97.2 (3.5)	20.4	45.7 (0.5)
	Low	28.9	83.9 (3.8)	19.6	98.0 (4.1)	20.7	50.8 (1.7)
	High	30.4	89.9 (1.1)	20.9	91.7 (1.6)	20.4	57.4 (1.3)
Chadwick Bay	Bottom	30.9	71.5 (1.9)	18.5	91.1 (3.3)	20.1	52.4 (2.0)
	Low	31.0	74.9 (2.8)	19.5	96.7 (1.3)	21.4	51.0 (2.2)
	High	30.9	89.4 (1.1)	18.5	93.4 (1.4)	20.1	50.7 (1.7)

only when oysters were raised on high racks (Table 2 and Fig. 5c). For the marginally significant (Table 2, $P = 0.05$) interaction between site and elevation, elevating oysters affected oyster survivorship only at Newport River, where survivorship of oysters was significantly greater on high racks than on the bottom.

Incidence of Oyster Disease and *Polydora* spp. Infestation

The prevalence (% of oysters infected) and intensity of *P. marinus* infection was extremely low at all sites for oysters tested in both August (1.7% were infected) and October 2001 (3.3% were infected; Table 4). In August, *P. marinus* was detected at only 1 to 2 sites for each of the 3 species, and its average prevalence for any species at any site was never greater than 10.0% (Table 4). In October, *P. marinus* was detected in *C. ariakensis* at 4 of 7 sites, and was most prevalent (16.7%) among *C. ariakensis* on low racks in Newport River and most intense (0.67) among *C. ariakensis* at Topsail Sound (Table 4). Of the 3 species, *P. marinus* was least prevalent and least intense among *C. gigas* and was detected only among *C. gigas* on high racks at Chadwick Bay in October (Table 4). *P. marinus* was detected in *C. virginica* at 4 of 7 sites in October (see Table 4).

In August 2001, the prevalence (% of oysters infected) and intensity of *Polydora* spp. infestation were greatest among *C. ariakensis*, intermediate among *C. gigas*, and almost nonexistent for *C. virginica* (Table 5). Prevalence and intensity of mud worms on *C. ariakensis* shells were very high at Broad Creek and Swan Quarter Bay, intermediate at Chadwick Bay, and very low at the other 4 sites (Table 5). Mud worm tubes were present on over half of *C. gigas* oysters tested at Chadwick Bay, but were present at only 1 of the other 4 sites (6.7% at Waters Bay; see Table 5). Waters Bay was the only site where mud worm tubes were present on *C. virginica* oysters (Table 5). In October 2001, mud worm

prevalence and intensity were greatest among *C. ariakensis* and *C. gigas*, and almost nonexistent among *C. virginica*. Mud worms were present on *C. ariakensis* and *C. gigas* shells at all sites except Waters Bay and Topsail Sound, and were most prevalent and intense at Chadwick Bay (Table 5). For *C. virginica*, mud worms were detected only at Chadwick Bay on high racks. In October, both infestation prevalence and intensity on shells of *C. ariakensis* and *C. gigas* were slightly greater on low racks than on either the bottom or high racks.

DISCUSSION

Critical to any decision on the introduction of non-native species for aquaculture, fisheries, or restoration of ecosystem services once provided by native species is an assessment of the biology of the candidate species in their prospective new environment. The primary motivations for introducing 1 of the 2 non-native oysters to Chesapeake Bay are their presumed resistance to *P. marinus* and *H. nelsoni*, with consequent survival advantages over the native oyster, and their high individual growth rates (National Research Council 2003). Previous studies comparing non-native oysters to *C. virginica* have found that the 2 non-native species tend to grow and survive better than the native oyster (Barber & Mann 1994, Calvo et al. 1999, Calvo et al. 2001), although reducing salinity can decrease or eliminate the growth and survivorship advantages of *C. gigas*. Barber and Mann (1994) demonstrated that growth and survivorship of *C. gigas* grown in the Chesapeake Bay were negatively impacted by salinities below 20‰. Similarly, Calvo et al. (1999) found that growth and survivorship of *C. gigas* in Chesapeake Bay were reduced at an intermediate salinity range of 15‰ to 25‰ in contrast to sites with salinities consistently above 25‰. They also noted that the individual growth rate of *C. gigas* was no longer greater than that of *C. virginica* at this intermediate-salinity

TABLE 4.

Prevalence and intensity of the oyster disease *Perkinsus marinus* among native and non-native oysters grown at 7 field sites in North Carolina. *P. marinus* prevalence and intensity were examined in August and October of 2001.

^a Infection intensity was calculated using the method described by Ray (1954) and Mackin (1962), with infection intensity categorized into the following groups: (0) absent, (1) light, (3) moderate, (5) heavy (Calvo et al. 1999, Lenihan et al. 1999). Average weighted intensity of dermo then was calculated for each species at each site by multiplying the number of oysters with each infection level by its infection intensity and dividing this sum by the total number of oysters tested.

TABLE 5.

Prevalence and intensity of mud worm *Polydora* spp. infestation among native and non-native oysters grown at 7 field sites in North Carolina. Mud worm infestation levels were quantified in August and October of 2001.

Intensity of *Polydora* spp. shell infestation was rated on a scale of 0 to 4 to approximate the percentage of the oyster shell covered by mud worm tubes ([0] absent, [1] <25%, [2] 25–50%, [3] 50–75%, and [4] >75% coverage; Calvo et al. 1999). Weighted intensity was calculated by multiplying the number of oysters with each intensity level by their respective infestation intensity and dividing the sum by the total number of oysters tested.

level. Calvo et al. (2001) found low mortality rates for *C. ariakensis* over a wide spectrum of salinities (<15‰, 15‰ to 25‰, >25‰), suggesting that the physiology of *C. ariakensis* is influenced less by salinity than that of *C. gigas*. High *C. virginica* mortality rates in 2 of these studies (Barber & Mann 1994, Calvo et al. 2001) were primarily caused by the parasitic protozoan *P. marinus*, which is one of the largest impediments to native oyster aquaculture and recovery of native oyster fisheries in the estuaries of Maryland and Virginia. Prior to our study, growth and survivorship of the two non-native species had yet to be compared along the Atlantic coast of the United States, though Robinson and Langdon (1993) found that *C. gigas* growth was greater than that of *C. ariakensis* at sites on the West coast.

Results of our study provide clear evidence that the 2 non-native oysters, *C. gigas* and *C. ariakensis*, differ dramatically from one another and from the native eastern oyster, *C. virginica* in critical biologic rates (Table 6). As anticipated from previous studies done in the Chesapeake Bay (Barber & Mann 1994, Calvo et al. 1999), we found that *C. gigas* grows faster and survives at higher rates in high-salinity waters (25‰ to 36‰) than in 15‰ to 25‰ salinities. At the high-salinity sites, *C. gigas* exhibited consistent and substantial growth and survival advantages over the other 2 species (i.e., 162.4% higher growth than *C. virginica* and 54.1% higher than *C. ariakensis* and 33.1% higher survivorship than *C. virginica* and 22.3% higher than *C. ariakensis*). Thus, at high salinity, performance of the non-native *C. gigas* greatly exceeds that of the native eastern oyster in both biologic traits critical to production, namely growth and survivorship. From previous research (Barber & Mann 1994) and our own more limited data, the survivorship advantage of *C. gigas* could be related to greater resistance to *P. marinus* infection. At the 1 site of intermediate salinity (15‰ to 25‰) where we deployed *C. gigas*, it was sig-

nificantly outperformed in both growth and survival by the native eastern oyster, *C. virginica*. Therefore, any enthusiasm for introduction of *C. gigas* to Chesapeake Bay or the Pamlico Sound must be tempered by the realization that in the vast majority of the waters of these estuaries salinities favor the native eastern oyster.

Our results from deploying *C. ariakensis* in the small-scale grow-out trials confirm some previous conclusions from analogous research in Chesapeake Bay (Calvo et al. 2001) while providing new insights as well from direct contrasts with *C. gigas* and from our tests of elevation impacts. We first demonstrated in cold-season trials that salinity levels below 10‰ virtually inhibited all net growth and caused high mortality of *C. ariakensis*, thereby serving to help define one environmental and thus geographic limit to its successful culture. A site with salinity consistently below 10‰ proved unsuitable to achieve net growth in winter and simultaneously induced high mortality. The native eastern oyster actually significantly outperformed *C. ariakensis* at this low-salinity site in both growth and survival. However, the native oyster would have required an additional 3 to 4 y to achieve market size based on observed growth rates of *C. virginica* from this site, rendering such environments poor candidates for its culture also.

At sites of intermediate salinity (15‰ to 25‰), *C. ariakensis* significantly outgrew *C. gigas* by 35.9% and *C. virginica* by 24.5%. At intermediate salinity, *C. ariakensis* survivorship was 42.1% higher than that of *C. gigas*, but it did not differ significantly from *C. virginica*. However, the absence of a survival advantage of *C. ariakensis* over *C. virginica* in our study is misleading. By the time our trials were terminated, *C. ariakensis* had already reached a legally harvestable size (76.2 mm SH in North Carolina), whereas the more slowly growing native oyster had not. Using observed growth rates of *C. virginica* in our study, approximately 2–10 additional months of culture would have been re-

TABLE 6.

Summary of results from experimental culture of native (*C. virginica*) versus non-native (*C. ariakensis* and *C. gigas*) during 1999–2000 and 2001–2002 in North Carolina.

	Year	Site	Species Compared	Elevation	Results	
					Individual Growth	Survivorship
1. High-salinity (>25‰) sites

3. Low-salinity (<10‰) site ^b						
	1999–2000	Broad Creek, Wanchese	<i>C. ariakensis</i> versus <i>C. virginica</i>	Low elevation	virg > aria	virg > aria

^a *C. virginica* had not reached marketable size by the end of the experiment. Therefore, the 2–9 months of additional estimated grow-out would be expected to lead to much more mortality from dermo and other sources.

^b Abnormal environmental conditions following Hurricane Floyd resulted in extremely low salinity levels at Broad Creek in 2000 (Peterson 2000).

quired to achieve market size. The several additional months of warm water exposure required to complete grow-out of *C. virginica* would almost certainly have elevated its mortality, perhaps even dramatically if *P. marinus* infection had increased as expected (Lenihan et al. 1999).

At sites of high salinity, growth of *C. ariakensis* consistently and significantly exceeded that of the native *C. virginica* in all 5 trials where this contrast was set up. However, *C. ariakensis* survivorship was highly variable and unpredictable even using the environmental information on actual salinity, temperature, and DO variation that we collected. Over the 5 trials comparing *C. ariakensis* to *C. virginica* at high salinity, *C. virginica* survived at a significantly higher rate in 2 cases, *C. ariakensis* survived better in 2 cases, and no significant difference was detected in the remaining contrast. The high variability in the survivorship results for these 2 species at high salinity differs from the consistent advantage of *C. ariakensis* previously demonstrated in the Chesapeake Bay study of Calvo et al. (2001).

Comparison of triploid non-native oysters with diploid *C. virginica* could partly explain why non-native oysters outgrew *C. virginica* because reduced gamete production in triploids generally results in enhanced somatic growth (Barber & Mann 1994). Allen and Downing (1986) and Davis (1989) documented that triploid *C.*

gigas outgrow diploid *C. gigas*, particularly during the reproductive season. However, in a previous study with triploid *C. gigas* and *C. virginica*, *C. gigas* growth was nearly double that of triploid native oysters at high salinities (Calvo et al. 1999), suggesting that growth results in our study are only slightly confounded by differences in ploidy status among species.

A second potential limitation of this study was that the size and condition of oysters differed among species at the beginning of each experiment. In particular, *C. ariakensis* were approximately 10 mm (SH) larger than either of the other two species at the beginning of the experiment. *C. ariakensis* were raised at VIMS until they were large enough to be tested for ploidy status prior to use in this study. Because the proportional growth in oyster biomass increases with each incremental gain in shell height, an incremental gain in shell height for a larger oyster represents greater growth in biomass than the amount of biomass growth from a similar gain in shell height of a smaller oyster. Therefore, in this study growth rates of *C. ariakensis* are likely underestimated relative to the other two species. In particular, differences in growth rates between *C. gigas* and *C. ariakensis* were likely overestimated at high salinity sites, and *C. ariakensis* growth advantages over *C. virginica* and *C. gigas* (at low salinities) were probably underestimated. Another important consideration is that these oyster spe-

cies differ in morphology, so that an incremental change in SH for each species does not necessarily represent a uniform change in oyster biomass. Comparison of oysters tissue weights of larger (80–110 mm SH) oysters that did not differ in SH determined that *C. ariakensis* tissue weight was approximately twice that of *C. virginica* and one-third greater than *C. gigas* tissue weight (Grabowski et al. 2003). Thus, comparing growth rates by quantifying changes in shell height also underestimated *C. ariakensis* growth relative to the other two species.

Our experiment that varied the elevation of oysters from culture on the bottom to racks of 2 different heights, 15 cm and 38 cm, provides some insight into why the relative advantage of *C. ariakensis* may change among sites even with salinity held constantly high. Varying elevation off the bottom had no detectable impact on growth of *C. gigas* and did not change the survivorship advantage that *C. gigas* held over both other oysters. However, culturing *C. ariakensis* on the bottom consistently reduced its growth rate. Growth of *C. virginica* also exhibited lower growth in bottom culture at 1 of the 2 sites, but the native oyster was sufficiently less sensitive to the bottom environment such that the statistically significant growth advantage held by *C. ariakensis* over *C. virginica* at both rack elevations disappeared on the bottom at one site. Similarly, *C. ariakensis* held a detectable survivorship advantage over *C. virginica* only on high racks. Because the concentration of suspended sediments decreases dramatically with elevation in the water column in estuaries and suspended sediments can interfere with suspension feeding (Rhoads & Young 1970), our results from the manipulation of elevation of culture imply that *C. ariakensis* is more sensitive to elevated turbidity than the other two oysters. Consequently, variation in suspended sediment load may help explain the high variation in *C. ariakensis* survivorship among high-salinity sites. Such sensitivity to bottom culture implies that *C. ariakensis* may experience difficulty in becoming established in more turbid regions of estuaries.

Although results of our manipulation of culture elevation imply greater sensitivity of *C. ariakensis* to turbidity, it is doubtful that this explanation accounts for all the variation in its survivorship among high-salinity sites. Other factors varied among sites, such as extensive shell fouling by barnacles and tunicates at Newport River and Chadwick Bay, which may have contributed to mortality. Higher mortality rates could also be a consequence of the parasite *Bonamia* sp., which has caused extensive mortality among juvenile oysters in laboratory and field trials conducted at UNC-IMS (Bishop et al. unpublished data). Rearing organisms in hatcheries often results in extreme genetic bottlenecks (Gaffney et al. 1996, Launey & Hedgecock 2001), which could increase cultured species' susceptibility to parasites and diseases. In the absence of the ability to predict mortality from known independent environmental variables that could be measured *a priori* at any prospective aquaculture site, the possibility of high mortality renders culture of *C. ariakensis* in high salinity a very risky proposition.

Creating any structures rising more than 15 cm off the bottom in North Carolina waters requires growers to obtain a water column lease in addition to the standard bottom lease. Because water column leases historically have been very difficult to obtain in North Carolina and cost an additional \$100 per acre, advantages of using high racks must outweigh the added expense. Elevating oyster racks from 15 to 38 cm increased oyster growth and survivorship of *C. ariakensis* at both sites, growth of *C. virginica* at Newport River, and survivorship of *C. virginica* at both sites. The magnitude of the effects of increasing rack height from on the

bottom and at 15 cm to 38 cm was greatest for *C. ariakensis*, whereas elevating oysters to 38 cm did not affect growth or survivorship of *C. gigas* at either site. Elevating oysters from the bottom to 15 cm generally did not affect growth or survivorship for any of the 3 species. Our results suggest that oyster growers culturing *C. virginica* or especially *C. ariakensis*, but not *C. gigas*, might consider obtaining a water column lease, though a complete bioeconomic evaluation of whether increased growth and survivorship outweigh the additional costs should be considered first.

Our results from trial culture comparing the performance of 2 non-native oysters to the native eastern oyster provide reasonably clear conclusions. *C. gigas* consistently outperforms both other oysters in growth and survivorship in high-salinity waters, but does less well than the other 2 oysters in intermediate salinity. At high salinity, *C. ariakensis* can suffer extremely high mortality, perhaps in part from exposure to high turbidity or the parasite *Bonamia* sp., but the environmental determinants are not well enough known to predict where survival will be good or bad. Consequently, on the basis of unpredictable and occasionally massive mortality, culturing *C. ariakensis* at sites of high salinity is risky. On the other hand, *C. ariakensis* has a substantial growth advantage over both of the other 2 oysters at intermediate salinity and likely also has a survivorship advantage. The range of viable salinities for successful culture of *C. ariakensis* does not extend below approximately 10‰; however, in the range of 15‰ to 25‰, this oyster grows faster and suffers less from the oyster diseases that plague *C. virginica*. Elevation of *C. ariakensis* during culture should be a viable strategy to increase survivorship and growth, but the cost-benefit ratio of obtaining water column leases should be examined further in North Carolina. Incorporation of all these results into a bioeconomic model is now necessary to quantify and compare the additional value that could be generated from higher growth and/or survivorship rates of non-native species relative to the risks associated with introducing a non-native species.

Because oyster consumers in eastern North Carolina prefer *C. virginica* over either non-native species when consumed raw and *C. gigas* when eaten cooked (Grabowski et al. 2003), differences (if any) in the price of each species for both raw and steamer markets must be incorporated into economic evaluation of the profitability of culturing non-native oysters. Given that the added cost of producing triploid oysters to avoid wild introduction is high and non-native oysters may be somewhat less palatable, culture of triploid non-native oysters may prove economically non-viable. Making non-native oysters available for aquaculture may, however, lower the probability of unsanctioned and uncontrolled introduction of reproductively capable non-native oysters into the environment (National Research Council 2003), thereby reducing the risk of potentially dire ecologic impacts of introducing a non-native species (i.e., competition with native species, unintentional introduction of additional predators and/or diseases, etc.). Finally, potential ecosystem benefits (i.e., water filtration, habitat provision) of promoting bivalve aquaculture should also be considered in deciding about permits for culturing non-native oysters. The question of whether to attempt to establish breeding, self-replicating populations of a non-native oyster entails consideration of many more issues, but requires more biologic information on potential risks versus economic and ecosystem benefits.

ACKNOWLEDGMENTS

The authors thank Matt Kimble, Chris Stewart, Christina Tal-
lent, and Rachael Wagaman for assistance in culturing the oysters

in the field and conducting laboratory assays. Stan Allen, Jr., of the Virginia Institute of Marine Sciences provided disease-free triploid seed for both non-native oysters and much guidance. The authors thank Joe McClees, Carla Gwaltney, and numerous other supporters. This manuscript was greatly enhanced from comments by Sandy Shumway and two anonymous reviewers.

Mack Salter and Brian Sheppard also contributed their knowledge as commercial shellfishermen. This research was supported by the North Carolina General Assembly (through the Rural Development Foundation and the Fishery Development Foundation) and the North Carolina Department of Environment and Natural Resources.

ABSTRACT The gonadal development by estimating the percentage of cell components of the mantle (MC) of cultured oysters (*Crassostrea gigas*) and mortality were studied in the Bahía Falsa, B. C. México from May 1996 to April 1997. Two localities, inner and outer zones of the Bay, were considered. Oysters were grouped in accordance with their position in the culture art, upper, middle, and lower level. Differences among the percentage of developing gametes (DG) and ripe gametes (RG) were according to the locality of the Bay and the position of the oysters in the culture art. In the outer locality, ripe gametes started to appear in February and reached their maximum proportion in May and June (around 60%). There was a trend of minor percentages of DG and RG in the lower level. Reproductive activity extends to November in the upper and middle levels. From September to January the no reproductive period was in curse. In the inner locality the percentage of ripe gametes also started to appear in February but their percentages were higher (around 80%) in May and June than in the outer locality. The reproductive activity ends in September. Percentage of vesicular cells (VC) increased from June to January. There was minor percentage of DG and RG in the lower level. There was no relationship between the gonadic cycle and mortality of oysters but it was with the level of the culture art, and there was an increase in mortality values in the lower than in the middle and upper levels of the culture art and a major mortality in the outer than in the inner studied localities.

KEY WORDS: oyster, *Crassostrea gigas*, reproduction, gametogenesis, storage cells cycle, mortality

INTRODUCTION

The Japanese oyster *Crassostrea gigas* was introduced into several coastal lagoons of the Pacific coast of north west México, in 1973, including the Bahía Falsa, Baja California (Islas 1975). Nowadays the annual production in the region is approximately 1,622 mt with a value of 2.4 million dollars; approximately 1,800 employees are involved in this activity and Bahía Falsa contribute with 16% of these figures (Anuario estadístico de pesca, 2001).

The reproductive cycle of the Japanese oyster in Bahía Falsa was studied in the middle 1980s, when the raft culture was carried out (oysters remained underwater every time). Hernández-González (1989) studied oysters from one point in the inner area of the Bay and found that undifferentiated oysters are common in November, gametogenesis took place from March to June and spawning occurs from July to October. Paniagua-Chavez and Acosta (1995) studied two oyster populations in the middle and the outer areas of the Bay and found that spawning occurs from July to October in the outer area and from July to September in the middle area. Both studies were carried out using histologic analysis of the gonadal tissue. Currently the culture method used in the bay consists of wood frames, locally named "racas". Nylon ropes of 150 cm in length with attached oysters (named "sartas") are suspended from the racas (Fig. 1). Thus, oysters are affected by the tide; the oysters attached in the top of the line hang from the raca are exposed to air more time than those attached in the middle and bottom of the line. Moreover, food availability is also different in permanent submergence than in periodically exposed conditions. These differences may interact with the reproductive cycle of cultured oysters and have been recorded in other mollusks species like the blue mussel *Mytilus edulis*, *Mytilus galloprovincialis*, and *Mytilus californianus* from natural and cultured populations (Seed 1976, Ferrán 1991, Villalba 1995, Cáceres-Martínez & Figueras 1998, Curiel-Ramírez & Cáceres-Martínez 2004). The reproduc-

tive cycle is closely related with the meat content of oysters for harvest and the shelf life of the oysters, then knowledge of local variations in the reproductive cycle of oysters have a practical use for producers.

Some authors (Perdue et al. 1981, Beattie et al. 1988, Berthelin et al. 2000) have studied the probable relationship between gametogenic cycle and summer mortality in the Pacific oyster. The hypothesis of these studies is, after gametogenesis oysters became physiologically exhausted, and some mortality episodes can be related with that condition. Since 1998 some unusual mortalities have occurred in the Bahía Falsa, and the hypothesis of a pathogen agent involved has not yet been demonstrated (Cáceres-Martínez & Vásquez-Yeomans 2003, Curiel-Ramírez & Cáceres-Martínez 2004). Under the light of these findings, the study of the gametogenic cycle in cultured oysters exposed to different air exposition degrees during low tides and in different places of the Bay are relevant; moreover, the possibility that the gonadic cycle could be related with mortality episodes observed in the locality is also important.

This work was carried out to determine the gonadal cycle of the Japanese oyster *Crassostrea gigas* cultured at three different levels of the culture system and two localities in Bahía Falsa, Baja California, NW México and its relationship with mortality.

MATERIALS AND METHODS

The study was carried out in Bahía Falsa, Baja California, México from May 1996 to March 1997 (monthly samplings). Two localities, "Agromarinos" in the outer area of the bay and "Alfonsos", in the inner area of the bay were sampled (see Fig. 1). In each locality, one or two sartas carrying from 30 to 50 commercial size oysters were collected from the racas (mean total shell length, 12.73 ± 6.6 mm in Agromarinos; mean total shell length, 10.95 ± 3.1 mm in Alfonsos). The sartas, of about 150 cm in length, were divided into 50-cm sections: upper, middle, and lower levels (see Fig. 1). Approximately 10 to 20 oysters from each level were grouped separately for analysis. In Agromarinos the upper and

Figure 1. Map showing the inner (Alfonso's) and outer (Agromarinos) studied localities in Bahía Falsa, Baja California, Mexico. The oyster culture frames locally named "racas" and the nylon ropes where the oysters are placed named "sartas" are shown. For the study, oysters from the sarta were separated into three levels: upper, middle, and lower.

middle levels of the sarta are exposed to air during low tides, and the lower level of the sarta is always under water and never touches the bottom. In Alfonso's the entire sarta is exposed to the air during low tides and the end of the sarta touches the bottom on some occasions. During samplings, temperature ($^{\circ}\text{C}$) and salinity (ppt) in each locality were recorded with a conventional seawater thermometer and refractometer, respectively. Mortality was assessed by counting the number of empty shells from each sarta level every month, values showed cumulative mortality at each sarta level in the corresponding sampling month.

Live oysters were counted every month and after removing all fouling organisms with a brush and a jet of seawater, oysters from each level were measured (maximum axis as total length) and weighted (total wet weight). Oysters were opened and the meat was fixed in Davidson's fixative (Shaw & Batle 1957), and after 24 h an anterior transverse section was taken, including mantle tissue. Histologic sections with a thickness of $5\mu\text{m}$ were cut and stained with haematoxylin and eosin. The presence of gametes and storage cells were determined by quantitative sterology using a Weibel (1969) graticule, following the method described by Lowe et al. (1982). Briefly, five random counts were performed on each histologic slide. Results are given as a percentage of mantle volume occupied by the gamete development stages and cell types and defined as follows: ripe gametes (RG) in the female: it is the stage in which oocytes are free within the follicles and some oocytes remain attached to the follicle wall; whereas in the male: it is the stage when follicles are filled by spermatozoa arranged in

characteristic bands. Developing gametes (DG) in females: when rounded oocytes along with oocytes are attached to the follicle wall; whereas in the male: when varying quantities of developing spermatogenic cells are present. The presence of hemocytes around gametes and conditions of the follicle walls were recorded to determine if gamete reabsorption was occurring. The other cell components in the mantle were: vesicular cells (VC). Empty follicles (EF) were recorded when the points of the graticule indicate an empty area inside the follicle.

Differences between cell types (RG and DG) in the mantle volume per level of the sarta in each locality were assessed by a nonparametric Kruskal-Wallis ANOVA by Ranks test. Two way-ANOVA tests were used to compare significant differences of cell types in the mantle volume of *Crassostrea gigas* between localities. Student's *t*-test was used to compare significant differences between oyster mortality from Agromarinos and Alfonso's. A correlation between mortality and cell types (RG and DG) was carried out. Salinity and temperature were also compared with this statistical test.

RESULTS

Variations in percentage of the different cell types in the mantle volume of *Crassostrea gigas* from Agromarinos are shown in Figure 2. Presence of RG in the upper and middle level was recorded from February to November. In the lower level RG were observed from February to March and August. Reproductive ac-

Figure 2. Variations in percentage of the different cell types in the mantle volume of *Crassostrea gigas* from different levels of the sarta of the outer locality, Agromarinos.

tivity extends to November in the upper and middle levels. Reabsorbing conditions were similar in the upper and middle levels of the sarta. This activity seems to be different from those observed in the lower level, where the no reproductive season extends from September to February (VC reach values up to 70%). However, these differences were not statically significant ($H = 1.7$, $P = 0.89$). Samplings from June and July in the lower level were lost.

Variations in percentage of the different cell types in the mantle volume of *Crassostrea gigas* from Alfonsos are shown in Figure 3. In general, these variations show that the gametes maturation starts in February, reaching its maximum levels in May and June. Afterwards, there is a period of reabsorption of gametes, indicating the end of reproductive season in September. The no-reproductive season starts with the reabsorption of gametes in June continuing until February when the reproductive period starts. During that

time VC are in high percentages (up to 70%). These variations were very similar between the upper and middle level of the sarta, but the presence of RG and reabsorbing conditions in the lower level was minimal, these differences were significant ($H = 12.7$, $P = 0.02$). Samples from all levels of the sarta were losing in April.

A comparison of variations in percentage of the different cell types in the mantle volume of *Crassostrea gigas* between localities suggest that reproductive conditions (presence of RG and DG) are more frequent in the upper and middle levels from Agromarinos (outer locality) than in Alfonsos (inner locality) (see Figs. 2 and 3), and these observations were statistically significant ($F = 4.3$, $P = 0.03$).

In Agromarinos, the highest mortalities were recorded in July and March. There was a trend of higher mortality in the lower and middle levels, but not in the upper level of the sarta (Fig. 4A). In

Figure 3. Variations in percentage of the different cell types in the mantle volume of *Crassostrea gigas* from different levels of the sarta of the inner locality, Alfonso's.

Alfonso's, the highest mortalities were observed in February and March. The highest mortalities were observed in the lower level (see Fig. 4B). There was no correlation between the presence of RG and DG and mortality ($r = 0.09276$, $P > 0.05$). Mortality was higher in Agromarinos than in Alfonso's ($t = 2.54$, $P < 0.05$). There were no significant differences between mean temperature and salinity from both sample sites and their values exhibited similar monthly variations (t -test, $P > 0.05$) (Fig. 5).

DISCUSSION

A general scope of view of reproductive cycle in both localities and levels of the culture art, showed a reproductive season from

middle winter to early summer. The maximum reproductive period was from middle to late spring. This pattern was close to those recorded by Hernández-González (1989) and Paniagua-Chavez and Acosta Ruiz (1995), these authors found a reproductive season from late winter to summer. Interannual differences in the reproductive cycle of the same species in the same locality may be related to fluctuations in the environmental conditions occurring in a particular year (Seed 1976).

A particular analyses of the studied reproductive cycles suggested that, differences in percentage of MC between the outer and the inner locality could be related to differential food availability. Lara-Lara and Alvarez-Borrego (1975), Millán-Núñez et al. (1982), and González (1997) found that chlorophyll was more

Figure 4. Percentage of mortality of *Crassostrea gigas* in, (A) the outer locality, Agromarinos and, (B) the inner locality, Alfonsos; at 3 levels in Bahía Falsa, Baja California, México.

abundant in the outer than in the inner part of Bahía Falsa. García-Esquivel et al. (2000) and García-Esquivel et al. (2003) found that shell growth rates were 1.5 times higher at the outer than the inner of the Bay. Thus, oysters from the outer area are placed in a food rich area, which could result in more energy available to gametogenesis, and, in consequence a more reproductive activity in contrast to the inner area. Statistical comparison of DG and RG of oysters from the three levels of the sarta in outer locality indicates that there are no differences. Placing loose samples during 2 months in the lower level of the sarta could affect that conclusion. The trend of minor reproductive activity in the lower level of the sarta seems apparent (see Fig. 3). In the inner locality, differences in the percentage of DG and RG indicate that reproductive activity is minor in the lower level of the sarta than in

the middle and upper levels, and in this case this is statically confirmed. This reduction in the reproductive activity could be related to micro environmental conditions. Detritus produced by the oysters has resulted in a muddy bottom where organic degradation is common (Villareal-Chávez 1993). These conditions could be detrimental for the oyster gametogenesis. In contrast, it seems that environmental conditions related to air exposition during low tides (i.e., temperature changes, food availability, desiccation) of upper and middle levels have a similar influence on the reproductive activity of the oysters placed at these levels of the sarta.

Contrary to the observations of Perdue et al. (1981), Beattie et al. (1988), and Berthelin et al. (2000), mortality was not related to the reproductive condition, high mortality values in the outer locality

Figure 5. Fluctuations of temperature ($^{\circ}\text{C}$) and salinity (ppt) in the 2 localities studied, (A) the outer locality, Agromarinos and; (B) the inner locality, Alfonsos in Bahía Falsa, Baja California, México.

took place in July and March, the end and starting of the reproductive season respectively. In the inner locality, highest mortality rates were observed in February and March at the start of the reproductive season. However, the observed mortality tendency (highest mortality values in the lower level of the sarta) in the outer and inner localities suggests that muddy bottom where organic degradation occurs (Villareal-Chávez 1993), could be related to oyster survival. Detailed studies on mortality and physiologic condition of oysters are needed.

The major mortality values recorded in the outer than in the inner locality could be related to the fact that the inner locality is located near a tide channel where the water current is fast and may favor renewal or exchange of water near the bottom (Gosline & Stewart 1962). In contrast, the outer locality is placed near beds of sea grass (*Zostera marina* L.), where water exchange is low (Gosline & Stewart 1962). The high cumulative mortality values recorded reinforce the hypothesis of a possible pathogen as a causal

agent (Cáceres-Martínez & Vásquez-Yeomans 2003, Vásquez-Yeomans et al. 2004). Salinity and water temperature values were similar in both sampling sites and they are considered as appropriated for Japanese oyster growth and survival (Imai 1982, Pauley et al. 1988, Kennedy et al. 1996).

Usefulness of this information is related to the condition of the oyster for market, high meat content suggest harvest time; however, very mature animals may spawn during marketing, reducing their shelf life. High mortality values in the lower level of the sarta, suggest that placing sartas near the bottom should be avoided.

A COMPARISON BETWEEN A SUCTION DREDGE AND A TRADITIONAL OYSTER DREDGE IN THE TRANSPLANTATION OF OYSTERS IN DELAWARE BAY

ERIC N. POWELL AND KATHRYN A. ASHTON-ALCOX

Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Ave.,
Port Norris, New Jersey, 08349

ABSTRACT One mechanism to enhance oyster production is the timely transplant of oysters from nursery beds to beds used for commercial harvesting. Transplanting in Delaware Bay is normally done with a traditional oyster dredge. Such dredges can concentrate market-size oysters, a desirable characteristic for some transplant goals. Unfortunately, catch rates are slow. The suction dredge is much faster, but suction dredges likely do not concentrate large oysters and, by removing most surficial material, may reduce bottom shell coverage and decrease bottom complexity. We investigated the relative benefits of using a traditional oyster dredge and a suction dredge in a transplant program. In this study, traditional oyster dredges used for transplant operations had dredge efficiencies of approximately 5%, about 100 bushels of material being loaded per hectare swept. The tendency for the dredge to catch larger particles preferentially was negated by the tendency to operate the dredge at below-optimal efficiencies. Nevertheless, deck loads contained a factor of 2 to 3 more oysters per bushel than present on the bottom. The suction dredge operated very differently, although deck loads contained 1 to 3 times as many oysters as were present on the bottom. Catch efficiencies were high, between 19% and 58%. Swept area per bushel loaded was much lower, about 600 bushels being loaded per hectare swept. Catch efficiencies were highest for small particles. Dredge efficiency rose markedly after transplanting, from 6% to 28% on the plots worked by the traditional oyster dredge and from 11% to 56% on the plots worked by the suction dredge. Nevertheless, neither method proved deleterious to bottom complexity, cultch availability, oyster growth and mortality, or population health. In a sustainable transplant, the number of small oysters and amount of cultch moved should be minimized. This goal was not achieved. The suction dredge, by selective removal of smaller particles enriched in juveniles and cultch, risks a long-term decline in live oyster abundance and shell coverage. The traditional oyster dredge has the inherent capability of concentrating larger animals, but, as used in the transplant process, much of the selective advantage disappears. A behavioral shift to exploit the desirable selective advantage of the traditional oyster dredge may improve the efficiency of the transplant program.

KEY WORDS: oyster, *Crassostrea*, dredge efficiency, transplantation, fisheries management, Delaware Bay

INTRODUCTION

One mechanism to enhance oyster production is the timely transplantation of oysters from nursery beds to beds used for commercial harvesting (Owen 1953, Jory & Iversen 1985, Powell et al. 1997, Kraeuter et al. 2003). In Delaware Bay, nursery beds are in lower salinity water where lower predation rates and lesser disease prevalences increase oyster survivorship. Unfortunately, oysters frequently do not reach market size in harvestable numbers on these beds or, if they do, fail to achieve market standards of meat quality (Powell et al. 1997, Ford 1997, Kraeuter et al. 2003). Transplantation of these oysters downbay, however, normally results in a rapid increase in meat weight (condition) as well as increased growth (Kraeuter et al. 2003). Timed appropriately, such oysters can become marketable before the increased disease and predation pressure downbay markedly reduce their numbers. However, an efficient transplanting scheme would select from the nursery beds only oysters that can become marketable in one growing season, reserving on the seed beds smaller oysters requiring multiple growing seasons to achieve marketability; thereby minimizing loss to predation and disease.

In Delaware Bay, transplanting is normally done with a traditional oyster dredge. The dredge used by nearly all boats is a 24-tooth dry dredge, with tooth length approximately 44 mm, a mouth opening of 1.27 m × 51 cm, and a bag consisting of 17 rows of 50.8-mm rings (Fig. 1 in Powell et al. 2002). Dredge efficiency can exceed 50% (Powell et al. 2002), but is normally much lower (Chai et al. 1992, Powell et al. 2002), particularly when used during commercial harvesting (Banta et al. 2003). The dredge is less efficient for smaller oysters and much less efficient for cultch (Powell et al. 2002). A culling machine, an on-deck rotating drum

with bar spacing set to retain only the larger oysters and shell, can increase the concentration factor for market-size oysters (HSRL 2003). Hence, use of the traditional dredge and a culling machine should minimize downbay transport of small oysters that require more than one growing season to achieve market size.

Unfortunately, catch rates for dry dredges are slow. The average oyster boat moved 900 bushels[†] of oysters per day during the 2003 transplant program in Delaware Bay (New Jersey Department of Environmental Protection [NJDEP], pers. comm.). An alternative is the suction dredge. The suction dredge is essentially a large vacuum cleaner. Water is pumped through a hose from the bottom to the deck. As a consequence, the surface material under the dredge is vacuumed up through the hose to the deck, washed over a fine-mesh sorter to remove mud and sand, and then deposited on the deck. A suction dredge of 2.44-m swath can easily move 3,500 bushels in the time the dry dredge moves 900 bushels.

Suction dredges are often used to clean fouled shell from leased grounds, to move spatulated cultch after shellplanting, or to remove predators (Ismail 1985). In these activities, the objective is to remove virtually 100% of the surficial material. However, the transplantation of oysters downbay from nursery grounds must be done sustainably. Suction dredges, by removing most surficial material, may remove more cultch and small oysters than dry dredges (e.g., Ismail 1985), consequently reducing shell coverage on the bottom and, hence, bottom complexity, while transplanting small oysters downbay that will not survive to be marketed. On a per-bushel basis, the economic cost of using dry dredges is high, however; on this basis, a suction dredge might be the preferred tool

[†] A standard New Jersey bushel is 37 qt or 35 L.

COHANSEY GRIDS

NEW BEDS GRIDS

Figure 1. Location of transplant grid plots within the HSRL survey grid system (Fegley et al. 1994).

for transplanting. Accordingly, we carried out an investigation to determine to what degree use of a suction dredge, rather than a dry dredge, in transplanting might negatively impact the oyster population on the nursery bed, the anticipated long-term harvest from transplanting activity, and bottom habitat complexity.

METHODS

Experimental Design

Six contiguous experimental plots oriented in a 3 × 2 array were demarcated on Cohansey Bed in Delaware Bay (Fig. 1 in Banta et al. 2003). This bed historically has been an important nursery bed. Presently, oyster abundance on this bed and neighboring beds is at or above the 75th percentile of abundances recorded since 1989 (HSRL, 2003) when Dermo disease caused by the endoparasitic protozoan *Perkinsus marinus* first became epizootic in Delaware Bay (Ford, 1996). Two of these six plots,

HSRL survey grid plots 23 and 33 (Fig. 1, see also Fegley et al. 1994), each 0.2°-latitude × 0.2°-longitude or 26.3 acres (10.63 ha) in size, were assigned, one each, to 2 dry-dredge boats, the *F/V Mabel Hollinger* and the *F/V Robert Bould*. Two plots of the same size, HSRL survey grid plots 24 and 32 (Fig. 1, see also Fegley et al. 1994), were assigned to a suction dredge boat, the *F/V Jeanne Christine*. The final two plots, each 0.1°-latitude × 0.2°-longitude subdivisions of HSRL survey grid plot 34 (Fig. 1), of 13.15 acres, were designated unfished controls.

A preliminary survey of the four experimental plots was conducted by a vessel of known dredge efficiency (Powell et al. 2002), the *F/V Howard W. Sockwell*, on May 9, 2002. In New Jersey, the number of oysters transplanted yearly from the nursery beds normally has been limited to 10% of the standing stock ≥63.5 mm in size (HSRL, 2003). We chose, in designing the experiment, to exceed this goal on experimental plots by about a factor of 2 so as to evaluate the effects of a suction dredge at a level of impact

unlikely to occur routinely in the transplant program. Thus, 20% of the total number of ≥ 63.5 -mm oysters within each grid plot was targeted for transplant. Accomplishing this exceeded the allocated 1-day for each of the dry-dredge boats, but took less than 1 day per plot for the more efficient suction dredge. Oysters and cultch put on deck were transplanted downbay to New Beds HSRL survey grid plot 2 (Fig. 1 in Banta et al. 2003, see also Fegley et al. 1994). The suction dredge boat transplanted to a single 0.1°-latitude \times 0.2°-longitude section of this plot. The two dry-dredge boats transplanted to a contiguous section of the same size. An abutting plot to the south, HSRL survey grid plot 10, was used as a control.

The volume of material moved downbay by each boat was estimated geometrically. Detailed measurements of the accumulated material on deck were taken and the pile approximated as a series of prismatoids and cones that provided volumetric calculations from measurements of diameter and height at various locations.

Onboard Sampling During Transplanting

One-bushel samples were taken hourly for the dry dredge and half-hourly for the suction dredge during the dredging process. On the dry-dredge boats, paired samples were taken from the hopper, representing the material coming out of the dredge, and from the pile, representing material sorted for retention by the culling machine. This latter cull was transplanted downbay. On the suction dredge, a single bushel sample was taken because no culling occurred on deck.

Bed Sampling—Dredge

Each of the four experimental Cohansey plots, one of the Cohansey control plots (34B), and the New Beds experimental plot was sampled prior to the transplant on May 9, 2002, using the *F/V Howard W. Sockwell*. Each Cohansey experimental plot, both control plots, and both New Beds transplant plots were sampled soon after transplant on July 15, 2002, approximately 4 months later on November 5, 2002, and approximately 10 months later, on May 6, 2003, using the *F/V Howard W. Sockwell*. The New Beds control plot was sampled on May 6, 2003. During the approximately 10 months that elapsed between transplant and final sampling, the New Beds transplant was closed to fishing by the NJDEP. Banta et al. (2003) estimated that yearly swept area by the Delaware Bay oyster dredge fishery on New Beds equals about 101% to 123% of bed area; hence the need to close this experimental plot. The Cohansey plots were not closed because dredging by the Delaware Bay oyster fishery on these plots used nearly exclusively for transplanting has varied between 11% and 36% of bed area (Banta et al. 2003). Thus, little dredging was anticipated during the experimental time. Unfortunately, some removals may have occurred from the control plots during the oyster industry's late summer of 2002 transplant.

Each sampling time, three random 1-min tows were taken in each plot. Following transplanting, these samples were distributed randomly within the subsection of the plot from which most transplanted material was obtained. DGPS position was recorded every 5 seconds. All material caught by the dredge was volumetrically measured. A 1-bushel subsample from each dredge haul was retained for further analysis.

Bed Sampling—Diver

Divers were used to obtain quantitative samples prior to the transplant on June 10, 2002, just after the transplant on June 24,

2002, and about 10 months later, on April 28, 2003. Diver sampling was limited to the Cohansey plots because we were interested in the effect of dredging style on habitat complexity on the nursery bed. Initially, five sites were randomly chosen within each Cohansey plot. Following transplant, two of the five locations were resampled. The remaining three were randomly distributed within the area of the plot from which most of the transplanted material was obtained. A buoyed 23-m transect line was dropped from the *R/V Zephyrus* at each site. Twelve collection bags were affixed at equal intervals along this line. Divers were then deployed to retrieve all loose bottom material, including live oysters and boxes (dead, articulated valves) within a 0.25-m² quadrat haphazardly deployed at each collection site. The divers were instructed to take only the loosely consolidated material on the surface that would normally be taken by the dredge. In most cases, quantitative retrieval was simple because the consolidated portion of the bed was near the surface. In a few cases, unconsolidated shell extended downwards for some distance. In these cases, the diver took the upper portion of the shell until the collection bag was filled.

Laboratory Analysis

Diver quadrat samples and dredge-boat bushel samples were identically analyzed with three exceptions noted subsequently. Each bushel or quadrat sample was sorted into live oysters, boxes, cultch, and debris and the respective volumes measured. Debris includes such miscellany as rocks, gravel, and detached bionts such as sponges and erect hydroid/bryozoan colonies. Cultch was defined as single valves and shell fragments without attached live oysters or boxes. The assumption was that boxes represented recent mortality (Christmas et al. 1997). The longest dimension (anterior-posterior) of the right valve of each oyster and box >20 mm was measured. Live spat, oysters <20 mm, were tallied.

Clumps were defined as composites containing some combination of two or more shells, boxes, and/or live oysters. The 10 largest clumps in each bushel or quadrat sample, or all of the clumps if fewer than 10, were analyzed. The average number of clumps in a set of samples so derived is termed "minimum average" henceforth. The length and height of each chosen clump were measured. Maximum clump cross-sectional area (A) for these selected clumps was defined as: $A = \text{clump length} \times \text{clump height}$. The number of oysters, boxes, and spat per clump was enumerated.

Dry meat weights were taken for 20 oysters per bushel. Condition index was defined as:

$$CI = \frac{\text{dry weight (g)}}{\text{length (cm)} \times \text{height (cm)}}$$

For New Beds samples taken on May 6, 2003, 20 oysters per bushel were taken for *Perkinsus marinus* analysis following standard procedures (Powell & Ellis 1998).

Samples obtained during the transplant program onboard the *F/V Mabel Hollinger*, the *F/V Robert Bould*, and the *F/V Jeanne Christine*, were analyzed simply to estimate the number and size frequency of oysters present.

Estimation of Dredge Efficiency

Dredge efficiency, e , was estimated by comparing dredge samples of unknown efficiency to diver samples of known (100%) efficiency:

$$e = \frac{\left(\frac{\text{number of oysters or boxes (bushel)}^{-1} * \# \text{ bushels}}{\text{m}^2 \text{ dredge swept area}} \right)}{\left(\frac{\sum_{i=1}^{12} \text{number of oysters or boxes (diver sample)}^{-1}}{\text{number of diver samples} * 0.25 \text{ m}^2} \right)} \quad (1)$$

Because all comparisons were made on a 1-m² basis, the catchability coefficient q (Powell et al. 2002) was defined as the reciprocal of efficiency e :

$$a = \frac{1}{e}.$$

Sampling was carried out by diver and by the *F/V Howard W. Sockwell* using a traditional oyster dredge in survey mode. The term "survey mode" refers to the sampling protocol in which tows were of 1-min duration and catches never filled the dredge bag. Dredge efficiencies tend to be relatively high in this use (Powell et al. 2002). Estimates of dredge efficiency represent averages for each grid for each sampling time because diver transects were not conducted simultaneously with dredge-boat sampling and because diver transects were not oriented in or parallel to dredge-boat tow paths; thus, pairwise comparisons between a single diver transect and a single dredge-boat tow could not be made.

Statistical Analysis

For most analyses of dredge-boat samples, metrics, such as the number and volume of live oysters, were expressed on a per bushel basis rather than as a quantitative measure (m⁻²), because, in the case of bushel samples from the transplant boats, the bushel sample did not come from a known area and because transplanting is inherently a volumetric activity rather than an areal activity. Samples taken by the *F/V Howard W. Sockwell* were also quantitated using a correction for dredge efficiency obtained from quantitative diver samples and measured swept area from DGPS positions taken during the tow. Because of the limited number of dredge efficiency measurements and the scale of these corrections, significant differences between treatments must be provisional.

On the other hand, the use of volume standardization assumes an invariant cultch volume per bushel. Because cultch was not invariant, because live oysters comprised a significant fraction of the total volume, and because live oysters were preferentially removed in some treatments, statistics based on volume standardization also must be considered carefully.

The two sampling approaches, diver and dredge boat, each have their strengths and shortcomings. The dredge boat integrates a large area, but is not directly quantitative. The diver sampling is quantitative, but the smaller area sampled may be less representative of the total plot because dredging intensity during transplant was unevenly distributed and because of the inherent patchiness of oysters on the bed. Thus, we looked for trends that were sustained by both volume and quantitative standardization and for trends that were sustained by both dredge and diver sampling.

Most statistical analyses used ANOVA. Unless otherwise noted, all variables were ranked prior to analysis; thus most analyses are nonparametric (Underwood 1981, Sokal & Rohlf 1998). The experimental protocol for dredge sampling involved a nested series of samples, in that each Cohansey treatment had two replicate plots and each replicate sampling involved analysis of three 1-bushel samples per plot. Similarly, diver samples involve a nested set of 12 samples within each string, five strings nested

within each plot, and two plots per treatment. All ANOVA models were so designed.

Because no reason except proximity supported the assumption that control areas were representative of experimental areas, comparisons involving the effects of transplant were judged primarily by the significance of time \times location interaction terms. That is, we assumed equivalency of environment over the Cohansey (and New Beds) area used for our experiment, so that natural temporal changes should have been relatively uniform and, consequently, the time \times location interaction term would be insignificant without significant perturbation by the experimental manipulation of oyster transplant.

Whenever the desire was to conduct analyses on ratios of variables, such as condition index, the denominator was used as a covariate and the numerator as a dependent variable to avoid the increased variance that often accompanies ratios (Green 1986, Sokal & Rohlf 1998). Analyses evaluating the variance used the mean as a covariate because the variance normally increases with the mean (Elliott 1977, Green 1989). For each diver sample, we measured total volume collected and, as well, the volumetric contribution of shell, live oysters, boxes, and debris, to the sample. For tests in which volumetric subsets were dependent variables, the total volume was used as a covariate.

Size frequencies were compared using percentiles, normally the 25th, 50th, and 75th, and the mean size, to permit comparison with the main effects of time and treatment. Because the objective of transplant was to move market-size animals downbay, the size-frequency distribution was also investigated using the proportional contribution of small (<63.5 mm), submarket (63.5–<76.2 mm), and market-size (≥ 76.2 mm) individuals. Analyses evaluating proportional shifts among these 3 size groups used small or submarket abundance as the dependent variable and market-size abundance as the covariate.

The evenness in the distribution of dredging effort over the experimental plots was evaluated using Elliott's D (Elliott 1977):

$$D = \sqrt{\frac{\sigma^2}{\bar{x}} 2(n-1)} - \sqrt{2(n-1)-1} \quad (2)$$

where σ^2/\bar{x} is the variance-to-mean ratio. The metric used was the number of times the dredge was towed through each 0.01° latitude \times 0.01° longitude section of the plot.

RESULTS

Volume Transplanted and Concentration Factor

Between 445 and 1,504 bushels were transplanted from each experimental plot (Table 1). These values represent 10.8% to 27.1% of the standing stock of ≥ 63.5 -mm oysters estimated to be present prior to transplant. The suction dredge removed material more rapidly and so transplanted a higher fraction of the standing stock than the dry dredge in the allotted time (Table 1). The suction dredge boat also distributed its effort more evenly over the experimental plots (Fig. 3) than the dry-dredge boats (Fig. 2), although dredging effort was significantly contagiously distributed in all plots ($\alpha = 0.05$). Values of Elliott's D for the suction dredge were 22.2 for plot 32 and 33.8 for plot 24. Values for the traditional oyster dredge were much higher: 111.3 for plot 23 and 106.5 for plot 33. The increased and more unevenly distributed effort of the dry-dredge boats is in keeping with the standard operating procedure of these boats (Banta et al. 2003). Thus, the removal fractions

TABLE 1.

The number of bushels transplanted from each Cohansey plot, the fraction of the estimated oyster standing stock moved, the swept area covered during transplant operations, and the efficiency of extraction of live oysters from the bottom [i.e., equation (1)]. The catchability coefficient (q) is obtained as the reciprocal.

Treatment Plot	Bushels Transplanted	Fraction of Estimated Market-Size Abundance	Swept Area (ha)	Catch Efficiency
33 (Dry-Dredge)	445	11.6%	4.19	0.055
23 (Dry-Dredge)	608	10.8%	6.47	0.054
24 (Suction-Dredge)	1,504	15.8%	2.65	0.190
32 (Suction-Dredge)	1,131	27.1%	1.82	0.582

estimated in Table 1 are considerably higher in the areas concentrated upon, particularly by the dry-dredge boats, than for the plot as a whole. Dredge and diver sampling focused on these areas subsequent to transplanting.

We compared the number of oysters per bushel and their size frequency between the material brought onboard by the dry dredge

(in-hopper, Table 2) and the material subsequently culled by the culling machine and placed on the deck for transplant (on-deck, Table 2). The culling machine strongly selected in favor of ≥ 6 -cm particles (Fig. 4, Table 2). Culled material deposited on deck was enriched by a factor of 1.5 to 3.0 in these large particles relative to that brought onboard by the dredge (hopper-to-deck concentration factor, Table 2). Because many of these large particles are live oysters, on-deck culling concentrates submarket and market-size oysters. Live oysters loaded onto the deck for transplant ranged from about 1.5 to over 3.0 times more abundant per bushel of material than their proportion in diver samples taken directly off the bottom prior to transplant (bottom-to-deck concentration factor, unstandardized, Table 2). Thus, oysters were concentrated with respect to cultch. The size-frequency structure of oysters on the bottom and on the deck was about the same, however (bottom-to-deck concentration factor, standardized, Table 2), indicating that, in these two transplant experiments, the dredge tended to catch proportionately more small oysters while on the bottom and this counterweighed the culling machine's bias favoring larger oysters (Fig. 4).

The suction dredge operated in a distinctively different mode. Material brought on deck was underrepresented by large particles, including live oysters, relative to that on the bottom. Concentration

Figure 2. Contours of the frequency that an area was dredged during the course of transplanting from plot 23. The *F/V Robert Bould* carried out this transplant using a traditional oyster dry dredge. Contours are the number of times the dredge was taken through a 0.01° latitude \times 0.01° longitude rectangle, an area of 265.7 m^2 .

Figure 3. Contours of the frequency that an area was dredged during the course of transplanting from plot 32. The suction dredge boat, the *F/V Jeanne Christine* carried out this transplant. Contours are the number of times the dredge was taken through a 0.01° latitude \times 0.01° longitude rectangle, an area of 265.7 m^2 .

factors for oysters $\geq 6 \text{ cm}$ were often half or less of that observed for smaller oysters (Fig. 5, bottom-to-deck concentration factor, standardized, Table 3). The selection ratio between 4-cm and 7-cm oysters was 2.7 and 2.8 for the two transplants: the suction dredge was nearly three times as efficient in capturing 4-cm oysters as 7-cm oysters (Fig. 5). The equivalent values for the dry dredge were 0.9 and 0.8. The ratios of live oysters per bushel on the deck and on the bottom, 2.61 in one case (likely an overestimate—Table 3) and 1.16 in the other (Table 3), indicate that the suction dredge tends to concentrate live oysters relative to culch, albeit biased in favor of smaller individuals. Equivalent ratios for the 2 dry-dredge transplants, 2.64 and 2.46, averaged higher and the deck loads contained more large live oysters (Table 2). Note, in particular, that fewer of the largest oysters were loaded on deck by the suction dredge than were encountered on the bottom (bottom-to-deck concentration factor, unstandardized, Table 3). No size class was equivalently undersampled by the dry dredge (bottom-to-deck concentration factor, unstandardized, Table 2).

Estimates of Dredge Efficiency

During transplant operations, the suction dredge covered an area of 1.8 and 2.6 hectares to extract 1,100 and 1,500 bushels of

material, respectively. An experimental plot was 10.63 hectares, so the suction dredge covered an area equivalent to 17% to 24% of the total plot area. Catch efficiency for live oysters (Eq. 1) varied from 19% to 58% (Table 1).

By comparison, the dry dredge covered an area of 4.2 and 6.5 hectares to extract 450 and 600 bushels of material, respectively, an area equivalent to 40% to 61% of the total plot area (Fig. 2). Catch efficiency was much lower than the suction dredge, about 5% (Table 1), a value similar to other reported catch efficiencies for traditional oyster dredges used in commercial mode (Banta et al. 2003).

In comparison, dredge efficiency of the *F/V Howard W. Sockwell* during sampling averaged much higher, 15% to 19%, than the 5% dredge efficiency for the equivalent gear during transplant operations, yielding an arithmetic-mean catchability coefficient of 6 to 7 (Table 4). We also present estimates of q as the least-square means or the average of least-square means for nonsignificant treatment-time pairs in Table 5 for later use in converting volumetric measures (bushel^{-1}) from dredge hauls to quantitative areal measures (m^{-2}).

We used the estimated dredge efficiency for the *F/V Howard W. Sockwell* sampling in survey mode to monitor bottom consolidation, presuming that a decrease in bottom consolidation would

TABLE 2.

The number of oysters per bushel per 1-cm size class in the dredge hopper, on the deck after passing through the culling machine, and on the bottom prior to dredging for each Cohansey plot worked by the dry-dredge boats. The concentration factor is the ratio between the number on-deck and in-hopper or the number on-deck and on-bottom for each 1-cm size class after standardization of each sample to 100 animals per bushel. Bottom estimates were obtained from diver samples taken prior to transplant. The bottom-to-deck concentration factor given in parentheses without standardization includes the change in abundance within the size class as well as the proportional shift in size frequency.

result in increased sampling efficiency of the dredge. Dredge efficiency of the *F/V Howard W. Sockwell* varied significantly between sampling times ($P < 0.0001$, Table 6, Fig. 6). Whether the plot was a control plot, an experimental plot impacted by the dry dredge, or an experimental plot impacted by the suction dredge did not significantly influence dredge efficiency; however, the interaction term between treatment and time was significant ($P = 0.0017$) because the time-history varied for each treatment (Table 6, Fig. 6). Prior to transplant, dredge efficiency was lowest on the plots to be dry-dredged, but dredge efficiency varied only between 7% and 14% among both treatment and control groups. After transplant, dredge efficiency rose significantly in the two treatments to 32% and 39% for the dry dredge and suction dredge, respectively, whereas dredge efficiency on the control plot remained low at 17% (Fig. 6). Ten months later, dredge efficiency had fallen to 20% on the suction dredge plots, remained high on the dry-dredge plots (34%), and risen on the control plots (35%) (Fig. 6). Thus, dredge efficiency was lowest in all cases prior to transplant, then rose rapidly shortly after transplant in the two treatments, but not in the control plot. Dredge efficiencies were higher 10 months later in all plots, having risen to treatment levels in the controls by that time. Because we do not know the extent of possible industry dredging during the 10 months after transplant, the upward trend in the controls cannot be broadly interpreted. However, prior dredging by dry dredge or suction dredge increased sampling efficiency of the *F/V Howard W. Sockwell* shortly after transplant.

Oyster size also significantly influenced dredge efficiency ($P = 0.025$). Dredge efficiency was lowest for smaller oysters <63.5 mm (17%) and higher for the rest (30%) (Tables 4, 6). Although less often significant, this trend was true within treatments for all time comparisons and within times for all but one treatment comparison, the exception being just prior to transplant.

As a consequence of the significant time \times treatment interaction, we also examined the change in dredge efficiency within

treatment over time using, as a metric, the magnitude of change in dredge efficiency between sampling periods (bottom set of analyses, Table 6). Dredge efficiency changed little in the control plots over the period of transplant, but changed significantly in plots subjected to dry or suction dredging over the same period ($\Delta 25\%$ in both treatments). The degree of change in dredge efficiency in dredged plots was significantly higher than in the control (LS means test, versus dry dredge, $P = 0.0023$; vs. suction dredge $P = 0.011$). The change in dredge efficiency was much higher in market-size animals ($\Delta 32\%$) than submarket-size ($\Delta 18\%$) and significantly higher than smaller ($\Delta 7\%$) animals. The difference between the dredge efficiency shortly after transplant and 10 months later was significant, but now the only change of consequence was the change in dredge efficiency observed in the control plots ($\Delta 17\%$) in comparison to the change observed in the two treatment groups (Table 6).

Before-treatment Similarity in Dredge and Control Plots

Cohansey—Dredge Boat

Three random 1-min dredge tows were taken per plot prior to transplant on May 9, 2002. Significant differences were not observed between plots in the number of oysters, boxes, or spat, or the amount of cultch per bushel ($\alpha = 0.05$).

The cross-sectional area of the largest clumps averaged larger for the dredge samples than the diver samples (Table 7, 8), probably because the bushel sample obtained by the dredge was much larger than the volume sampled by a diver. Further analysis showed that average clump size of the 12 largest clumps collected by the divers much more closely approximated the maximum average clump size observed in the dredge samples, supporting this supposition. Clump cross-sectional area varied significantly among plots ($P < 0.0001$). An *a posteriori* test showed a complex array of relationships generally separating plots 23 and 24 with lower clump cross-sectional areas from plots 33 and 34. The num-

Figure 4. Cumulative size frequencies comparing the size structure of live oysters on the bottom, caught by the traditional oyster dredge (hopper), and passed through the culling machine to be transplanted downbay (deck). Numbers 23 and 33 refer to the grid plot numbers used for the experiment.

ber of oysters per clump also varied significantly among plots ($P < 0.0001$). Control plot 34B had clumps with significantly more live oysters per clump than any other. The same was not true for boxes.

Of the size-frequency metrics, only the 75th percentile of size varied significantly between plots ($P = 0.0055$), being significantly lower in plot 23 than plot 32. Thus, the largest oysters were larger on some plots than on others. The same was not true for boxes.

Cohansey—Diver Samples

Five random diver transects were sampled prior to transplant in each plot. The plots differed significantly in most measures prior to transplant, primarily because the volume of material per 0.25-m^2 collected on plot 32 destined for suction dredging was much

lower than the remainder and because proportionately more material collected from this plot was shell rather than live oysters, boxes, or debris. The trend carried through to the volume of culch ($P < 0.0001$). The two suction-dredge plots, 24 and 32, had the lowest culch coverage and the two dry-dredge plots, 23 and 33, had the highest (Table 9). The number of oysters per 0.25 m^2 also differed significantly between plots prior to transplant ($P < 0.0001$), as did the number of boxes ($P < 0.0001$). The control plot averaged higher than the others; plot 32 averaged considerably lower. Average clump cross-sectional area varied significantly between plots ($P < 0.0001$), being significantly smaller in plot 32. Not surprisingly, the number of oysters and boxes per clump also differed significantly among some plots ($P < 0.001$). Spat per 0.25 m^2 were significantly more common on the control plot ($P < 0.0001$) (Table 9); however the number of spat per clump did not

Figure 5. Cumulative size frequencies comparing the size structure of live oysters on the bottom and caught by the suction dredge to be transplanted downbay (deck). Numbers 24 and 32 refer to the grid plot numbers used for the experiment.

differ significantly between plots prior to transplant. Neither live oyster nor box size-frequency distribution differed significantly between plots prior to transplant. Finally, the average minimum number of clumps, defined as the 10 largest clumps or the total number of clumps if less than 10, differed significantly between plots prior to transplant ($P < 0.0001$) because plot 32 averaged fewer clumps than the remainder.

Overall, between-plot differences were more noticeable from the diver samples than the dredge-boat samples that integrated a much larger area of the bottom, but, in both cases, the size-frequency distribution was uniform, whereas oyster abundance and "clumpiness" differed. As a consequence, further analyses focused on time \times treatment interactions because between-treatment differences must be presumed to have originated from these prior differences in plot status.

Fate of Transplant Plots

Population Level Impact of Dredging—Near-term

Cohansey—Dredge Samples We compared treatment plots prior to and within 1 month after transplant. Treatments plots differed significantly (Tables 7, 10) only for the number of oysters per bushel. Very likely, this difference originated as plot differences prior to transplant. The time \times treatment interaction term was significant only for the number of oysters per clump (Table 10) which rose more in the plots subjected to the suction dredge (Table 7) than in the plots subjected to the dry dredge. A similar rise in the controls suggests that this result could be a sampling artifact. Similar results were obtained after a correction for dredge efficiency to quantify abundance (Table 5). The abundance of oysters and boxes

TABLE 3.

The number of oysters per bushel per 1-cm size class on the deck and on the bottom for each Cohansey plot worked by the suction-dredge boat. The concentration factor is the ratio between the number on-deck and on-bottom for each 1-cm size class after standardization of each sample to 100 animals per bushel. Bottom estimates were obtained from diver samples taken prior to transplant, except for plot 32. Divers collected an aberrantly low number of oysters prior to transplant on this plot. Accordingly, diver samples taken shortly after transplant were used. Numbers per bushel, thus, may be underestimated and concentration factors overestimated for this plot. The bottom-to-deck concentration factor given in parentheses without standardization includes the change in abundance within the size class as well as the proportional shift in size frequency.

did not vary significantly over treatment or time (# m⁻², Table 10), and the time × treatment interaction term was not significant.

Condition index varied significantly over time, as might be anticipated by the seasonal cycle of condition index in oysters (Hopkins et al. 1954, Haven 1962, Versar Inc. 2002), but the interaction term was not significant (Tables 10, 11). The size-

frequency distributions did not change significantly by any metric (Table 12). Because transplantation focuses on submarket and market-size animals, we also examined the proportion of small animals (<63.5 mm), submarket-size animals (63.5–<76.2 mm), and market-size animals (>76.2 mm). These proportions differed significantly over time, but the time × treatment interaction term was not significant (Table 10).

TABLE 4.

Catchability coefficients *q*, calculated as the reciprocal of dredge efficiency [equation (1)], for the sampling vessel, the *F/V Howard W. Sockwell*, using an oyster dredge in survey mode (Powell et al., 2002). Oyster size classes are market-size oysters, submarket-size oysters expected to grow to market size within one year (HSRL, 2003), and smaller oysters. Before, the initial sampling prior to transplantation; After, the sampling shortly after transplantation; Later, the sampling 10 months after transplantation.

Cohansey—Diver Samples Comparison can be made to the same analyses using diver samples. Neither time nor treatment exerted a significant main effect; however, the treatment × time interaction term was significant (Table 10) because a decrease in oyster abundance occurred, particularly in the dry-dredge plots relative to the controls (Table 8). The same was not true for boxes (Tables 8, 10). The treatment × time interaction term was significant for maximum clump cross-sectional area that declined on plots subjected to the dry dredge, but did not vary much in the control or suction-dredge plots (Tables 8, 10).

The number of oysters and boxes per clump did not vary significantly between treatments or over time (Table 10). The treatment × time interaction term was highly significant in both cases, however (Table 10). The number of live oysters and boxes tended to decline in plots subjected to dry dredging relative to the controls (Table 8). The number of spat per clump did not change significantly over time, nor did the average minimum number of clumps per m² (Tables 8, 10). The size-frequency distribution of live oysters and boxes did not vary over time by any of the five metrics used.

Population Level Impact of Dredging—Long-term

Cohansey—Dredge Samples We compared the condition of plots over a 10-month period after transplant. Not surprisingly, the number of oysters and boxes differed significantly over time, as

TABLE 5.

Quantitative estimates of oyster abundance for each treatment and date of sampling using the least-square means estimates of q obtained from statistical analysis of differences in catchability versus treatment (control, dry-dredge, suction-dredge) and date of sampling in Table 6. Average values of q were taken in cases where significant differences were not detected between treatments.

did the number of spat (Tables 7, 13). However, in most cases, these differences originated in the differences that originally existed between plots. Similar results were obtained after a correction for dredge efficiency to quantify oyster abundance (# m⁻²). The abundance of oysters and boxes did not vary significantly over treatment, but the abundance of oysters did change over time (Tables 7, 13). The time \times treatment interaction term was not significant. The time \times treatment interaction term was significant

for the number of oysters per clump and clump cross-sectional area (Tables 7, 13). Over 10 months, the number of oysters per clump declined in all treatments, but lesser declines occurred in the plots subjected to dry dredging (Table 7). Average maximum clump cross-sectional area declined, but only in the control plots.

Condition index varied significantly over time in accordance with the seasonal cycle, but the interaction term was not significant (Tables 11, 13). The size-frequency distribution changed signifi-

TABLE 6.

Results of ANOVA analysis of dredge efficiency using the comparison between the sampling dredge in survey mode operated by the F/V *Howard W. Sockwell* and the quantitative diver samples. Data and remaining details appear in Table 4. Treatment comprises the control plots, plots subjected to the dry dredge, and plots subjected to the suction dredge. Time represents the three sampling times, prior to transplant, shortly after transplant, and 10 months after transplant. After-Before, the difference between samples taken just before and just after transplant. Ten Months Later-After, the difference between samples taken just after transplant and about 10 months later. Size class represents market-size oysters, ≥ 76.2 mm, submarket-size oysters, 63.5 mm to < 76.2 mm, and smaller oysters, < 63.5 mm. —, not significant at $\alpha = 0.05$.

cantly over time (Table 13). Mean and median size rose, as did the 75th and 25th percentile (Table 12). The interquartile range changed little. Thus, growth occurred more or less equivalently on all plots. The time \times treatment interaction term was significant only for the interquartile range, and then barely so (Table 13). Because transplantation focuses on submarket and market-size animals, we also examined the proportion of small, submarket, and market-size animals. At this coarser level of resolution, the size-frequency distribution did not change significantly (Table 13).

Cohansey—Diver Samples Ten months after transplant, the number of live oysters had declined significantly (Table 13). The treatment \times time interaction term was highly significant (Table 13). Declines were largest in the controls; abundance was relatively unchanged in the suction-dredge plots (Table 8). The number of boxes did not vary much over time, nor was the interaction with treatment significant (Table 13).

Maximum clump cross-sectional area varied significantly over time. The treatment \times time interaction was highly significant (Table 13). The number of live oysters, boxes, and spat per clump all varied significantly over time and the interaction term with treatment in all cases was significant (Table 13). The number of

boxes per clump increased substantially in the control and suction-dredge plots in comparison to the dry-dredge plots (Table 8). The number of live oysters per clump declined, particularly on plots that had been impacted by the dry dredge and in the controls. The number of spat fell, particularly in control plots (Table 9); however, few spat were recorded in any plot. The minimum average number of clumps changed little (Table 13).

The size-frequency distributions changed significantly over time (median size, $P = 0.0028$; mean size $P = 0.0072$; 75th percentile, $P = 0.018$; 25th percentile, $P = 0.055$) because oyster size increased during the 10-months elapsed time in all plots and only a limited number of spat grew into the smaller size classes (Table 14). Size frequency was not significantly impacted by treatment.

Transplant Effects on Habitat Complexity

Suction dredges and dry dredges operate differently and might, thereby, differentially influence the small-scale structure of the bottom. We evaluated this possibility in a number of ways previously discussed, including the measurement of maximum clump cross-sectional area, the minimum average number of clumps

0.25-m⁻², and the number of live oysters and boxes per clump. We also examined complexity through analysis of the variability in the distribution of oysters and boxes using as descriptive metrics the variance between samples, the range of sample values, and the skewness and kurtosis of the sample values.

We first examined the variability between the 12 samples taken within each diver transect. The metrics were not significant for oysters or boxes, with the single exception of skewness among oyster values ($P = 0.044$). Nothing suggests that the distribution of sample values among samples within diver transects differed between treatments or over time. We also examined the variability between the five diver transects taken within each plot using the same four metrics. Once again, no significant differences were found in any of the four metrics.

Finally, we examined the proportional contribution of oysters, boxes, cultch, and debris to the volume collected by diver, on the

premise that removal of material during transplant should have influenced composition. Treatments never differed significantly in these volumetric proportions (Table 15). Time did significantly influence sample proportions, particularly live oysters and boxes (Table 15). Live oyster volume declined over time and box volume increased in most treatments. The time \times treatment interaction terms were significant in all cases except cultch volume (Table 15). For live oysters, a change in proportional contribution occurred because the volume of live oysters declined noticeably on control plots relative to either treatment over time (Table 9).

The expectation that cultch volume should be affected in some way led to a further examination of the variability in cultch volume among samples, as measured by the variance. The variance in cultch volume between samples on a diver transect was significantly higher 10 months after transplant than at earlier times, but the time \times treatment interaction term was not significant (Table 15).

Perhaps an effect on complexity can only be resolved by comparing bed status just before and just after transplant. We repeated each of the previous analyses, looking specifically at this time interval. No significant trends were revealed.

Fate of Transplants on New Beds

The number of oysters per bushel was not significantly elevated after transplant on either New Beds plot. Clump cross-sectional area declined significantly ($P < 0.0001$) from 71.4 cm² to 47.4 cm², however, and the number of oysters per clump increased from 0.7 to 1.8 ($P < 0.0001$). The size-frequency of live oysters did not change significantly, nor did the proportions of small, submarket, and market-size animals. However, condition index rose significantly in both plots, from the prior value of 0.049 g dry wt (cm² shell area)⁻¹ to 0.068 and 0.052 g dry wt (cm² shell area)⁻¹ for the dry-dredge and suction dredge plots, respectively ($P = 0.0007$). Thus, evidence that the oysters transplanted to New Beds changed population structure therein was revealed by a number of metrics.

The New Beds plots were followed for about 10 months after transplant to determine if the fate of the transplanted animals diverged between animals transplanted by dry dredge and by suction dredge. Few significant differences were observed between treatments or over time. Only a single time \times treatment interaction term was significant, for the number of oysters per clump ($P = 0.0024$). The number of live oysters per clump declined over the 10 month from 1.6 and 2.0 for the dry-dredge and suction-dredge transplants, respectively, to 0.5 and 0.7 in May 2003 ($P < 0.0001$). The number of boxes per clump simultaneously rose significantly from 0.13 and 0.13 to 0.60 and 0.50, respectively ($P = 0.0012$). The mortality occurred during a Dermo epizootic that recorded the highest overall oyster mortality on record for the 1989 to 2002 period (HSRL 2003). *Perkinsus marinus* prevalence and infection intensity were not significantly different between the transplant plots and the control plot in May 2003.

Condition index changed significantly after transplant, following the expected seasonal cycle, with highest values recorded in July 2002 and lowest values recorded the following November

($P < 0.0001$). During this 10-month period, the dry-dredge plots averaged significantly higher in condition index than the suction-dredge plots on each sampling occasion ($P < 0.0001$) (July, 2002: 0.068 vs. 0.052 g dry wt (cm² shell area)⁻¹; November, 2002: 0.035 vs. 0.026 g dry wt (cm² shell area)⁻¹; May, 2003: 0.051 vs. 0.039 g dry wt (cm² shell area)⁻¹). The time \times treatment interaction term, however, was not significant, suggesting that the differential between plots was established at the time of transplant.

DISCUSSION

Perspective

Oysters on the Delaware Bay nursery beds (Round Island to Cohansey beds, Fig. 1 in Banta et al. 2003) suffer relatively low annual mortality rates (Powell et al. 1997, Ford et al. 1999, Paraso et al. 1999), but do not routinely attain market quality due to small size and low condition index. Utilization of this resource requires downbay transplantation (Powell et al. 1997, Ford 1997, Kraeuter et al. 2003), whereupon submarket and market-size animals rapidly increase condition (Kraeuter et al., 2003) and relatively rapidly increase in size due to the increased food supply available at higher salinity (Powell et al. 1997, Versar Inc. 2002). Unfortunately, the higher salinity also brings with it markedly increased mortality rates from disease, principally Dermo caused by *Perkinsus marinus*, and, for small oysters, predation from crabs and oyster drills (Carriker 1955, Manzi 1970, Bisker & Castagna 1987). Thus, smaller oysters transplanted downbay requiring more than one growing season to reach market size will sustain considerable mortality prior to harvest.

The impact of oyster harvesting by tong or dredge has received much study (e.g., Marshall 1954, Lenihan & Micheli 2000, Mann 2000, Powell et al. 2001), but the specialized activity of transplanting has received much less. Oystering can significantly impact oyster populations and degrade oyster habitat (e.g., Rothschild et al. 1994, Peterson et al. 2000, Lenihan et al. 2001). Judging from the limited literature on transplanting, transplanting has not always been conducted sustainably (Moore 1911, Hargis & Haven 1988, Rothschild et al. 1994). Advantageous use of the oyster resource on the nursery beds of Delaware Bay has 3 requisites. (1) Large animals must be efficiently culled and moved downbay. These animals escape the increased predation rates and can be marketed quickly before disease mortality takes its toll. (2) The upbay nursery beds must be managed to achieve sustainable yield, in this case, sustainable transplant. (3) The transplant process must take place with limited long-term damage to the bed. Thus, transplant of shell should be limited as well as that of small live oysters.

The approach taken by New Jersey to ensure population stability on the nursery beds is to limit transplant to 10% of submarket + market-size abundance in any 1 year (HSRL 2003). This limits fishing mortality rate to a level generally considered sustainable (Rothschild et al. 1994, Klinck et al. 2001, Jordan et al. 2002). The transplant program also attempts to control the number of small oysters and the amount of shell transplanted downbay by limiting the fraction of the deck load that is cultch to $\leq 20\%$. But, the cost of this activity is high because oyster boats with culling machines, using traditional dry dredges, cannot move more than about 900 bushels per boat per day, typically at a cost of \$1.00 to \$2.00 per bushel. A suction dredge can move several times this quantity per day at a lower per-bushel cost. As a consequence, the suction dredge may be economically advantageous. However, use of the suction dredge must not compromise the requirements of sustainability, hence the motivation for this research program.

Operation of Dry and Suction Dredges

The traditional oyster dredge, a dry dredge, when towed in survey mode using short tows in which the dredge is retrieved without filling the bag, achieves dredge efficiencies on the order of 15% to >50% (Powell et al. 2002). Catch efficiency tends to be

much better for larger particles, including market-size oysters (Powell et al. 2002), as is true for most, if not all, types of shellfish dredges (e.g., Giguère & Brulotte 1994, Rudders et al. 2000, Volstad et al. 2000). Catch efficiency tends to be lowest for cultch, that is, single and fragmented valves without attached live oysters or

boxes (Powell et al. 2002). The survey dredge used for sampling in this study, onboard the *FIV Howard W. Sockwell*, behaved precisely as anticipated. Average dredge efficiency over all sampling periods was lower for the smaller size classes. Depending on particle size, dredge efficiency varied from 18% to 30%.

Under commercial operations, the dry dredge achieves a much lower dredge efficiency, typically below 5% (Banta et al. 2003). During commercial harvesting, oysters caught by the dredge are first passed through a culling machine, if one is installed, and then further hand-culled. The contrariety between survey and commercial operations arises from the fact that hand-culling onboard, required by marketing constraints, is much slower than the catching rate of the dredge. As a consequence, the dredge is left on the bottom longer than necessary, becomes overly full, and dredge efficiency necessarily then declines (Banta et al. 2003). Culling machines are used during transplant, but hand culling does not occur, and this speeds processing on deck. Nevertheless, for the culling machine to work properly, on-deck processing is still slow in comparison to the catching rate of the dredge. As a consequence, the dredge is left on the bottom longer than necessary and dredge efficiency necessarily then declines. Both dry-dredge boats used for transplanting in this study had dredge efficiencies of about 5.5%.

The propensity for allowing the dredge to remain on the bottom while deck culling proceeds, which leads to low dredge efficiency, has 2 unfortunate consequences. First, total swept area rises dramatically, about 100 bushels being loaded per hectare swept. Second, the tendency for the dredge to preferentially catch larger particles is negated: as the dredge fills, smaller particles are more likely to be retained. Presumably, larger particles can no longer easily fit into the bag. Catch efficiency rises for smaller particles including cultch and juvenile oysters, so material placed in the hopper for deck culling is enriched in precisely the less-desirable size classes targeted for culling and return to the bottom. Because the culling machine selects for the largest particles, the antithetical and unwanted effect of the overly-full dredge is largely counter-weighted. The final size-frequency distribution of the oysters on deck, integrating the two countervailing sorting processes, differs little from that present on the bottom. Clearly, the traditional oyster dredge as operated does not achieve the selectivity potential inherent in its design and desired in a sustainable transplant program. Despite the limitations however, the deck loads on the dry-dredge boats contained a factor of 2 to 3 more oysters per bushel than present on the bottom. So, cultch was selectively excluded, thereby protecting necessary substrate for the future larval settlement needed to replace oysters removed during the transplant process.

The suction dredge operated very differently. Catch efficiencies were high, varying between 19% and 58%. Total swept area is,

therefore, much lower for a given deck load. The suction dredge loaded about 600 bushels per hectare swept, about 6 times that achieved by the dry dredge. Efficiencies of 19% to 58% are in the same range as the catch efficiency of the dry dredge in survey mode.

The suction dredge has no onboard culling capability; consequently selection only occurs as material is removed from the bottom by the dredge. Nevertheless, the deck load averages 1.9 times more oysters per bushel than a quantitative sample of bottom material. However, suction dredging enriches the deck load in small particles, so that most of this increased abundance is small oysters. Presumably, some proportion of the larger animals escape capture because of their greater weight and concomitant larger sinking velocity or because they are more frequently affixed to the bed rather than lying loose on the bottom. Thus, surprisingly, both dredges as operated select similarly on the bottom, for small particles, the suction dredge being somewhat more successful in this undesirable trait. The amount of cultch retained differs dramatically, however. The deck load from the suction dredge was 62% cultch compared with only 27% for the dry dredge.

Effect of Dredging on Dredge Efficiency in Survey Mode

Dredge efficiency measurements are notoriously variable (e.g., Beukers-Stewart et al. 2001, Powell et al. 2002, NEFSC 2003). One typically ascribes this variability to the inherent variability of measurement and some controlling aspect of bottom condition. Powell et al. (2002) identified two regions in Delaware Bay that had consistently divergent dredge efficiencies, one with efficiencies averaging 65% for market-size animals and the other with efficiencies averaging 14% for market-size animals. Areas with characteristically high dredge efficiencies were on the downbay oyster beds used for commercial harvest and, thus, dredged frequently and intensively (Banta et al. 2003). Areas with characteristically low dredge efficiencies were upbay nursery beds in which dredging activity was limited (Banta et al. 2003). Powell et al. (2002) suggested that the difference in dredge efficiency could be ascribed to the degree of bottom consolidation that would vary with the frequency of dredging.

Both traditional dry and suction dredging break up the bottom. Sampling efficiency rose markedly after transplanting, from 6% beforehand to 28% afterwards for market-size oysters on the plots worked by the dry-dredge boat and from 11% beforehand to 56% afterwards for market-size oysters on the plots worked by the suction-dredge boat. At the same time, sampling efficiency rose from 10% to only 16% on the control plots. Anecdotal observations by oystermen suggest that bottom cohesion increases over the winter and then declines in the spring as the weather warms. Such a process would explain the small rise in dredge efficiency on the

control plots between May and July 2002. The more dramatic change on the dredged plots can only be ascribed to dredging breaking up the bed surface. The dry dredge does this mechanically as the dredge teeth are scraped over and forced to bite into the bottom. How the suction dredge operates to reduce bed cohesion is unclear. Perhaps the act of resuspending much of the fine material may permit the survey dredge, a dry dredge, to more effectively bite into the bottom or perhaps the impact of the suction process results in the material not entrained resettling onto the bottom in less consolidated condition. Regardless, the data conform with the previous suggestion of Powell et al. (2002) that some of the variability between dredge efficiency measurements can be explained by the recent history of dredging on the bed.

Interestingly, the dredge efficiency achieved on the control plots rose between July 2002 and May, 2003, as if these plots were impacted by dredging during that intervening period. The Delaware Bay oyster industry carried out its yearly transplant program in August 2002. Reports from participating oystermen indicate that some dredging may have occurred on the control plots at that time. As discussed later, additional information is available from this study that supports the verity of these reports.

Effect of Dredging on the Nursery Bed Population

The transplant efforts resulted in the removal of 11% to 27% of the market-size oysters estimated to have been present on these plots prior to transplant. The suction dredge operated more evenly over the entire plot and at minimal swept area coverage. The dry-dredge boats concentrated on selected sub-areas of the plots and at a substantially higher swept-area coverage. All transplant resulted in the removal of a quantity of animals at or above the level permitted in the present transplant program operated by the industry, a level set at 10%.

Obtaining equivalent population characteristics, even from abutting plots, is unlikely in the patchy world of the oyster bed (Powell et al. 1987, 1995, 2001; Calvo et al. 1996). Our set of plots was not exceptional in this regard. They differed in most population characteristics associated with volumetric or quantitative coverage, although proportional characteristics, such as size class composition, varied infrequently. As a consequence, statistical analyses focused on the degree to which plot attributes changed relative to one another, as revealed by interaction terms between time and treatment.

We examined two time dimensions. The first covered the immediate impact of transplant by comparing the bed just before and just after transplanting. This comparison was partly compromised by the inability to predict *a priori* where the dredge boats would focus their efforts. Consequently, the samples taken prior to dredging did not necessarily reflect the conditions of the dredged portion of the plots. The second time dimension, the succeeding 10 months after transplant, is not encumbered by this uncertainty.

We evaluated the effects of transplant by (1) sampling using a traditional oyster dredge in survey mode to provide volumetric (bushel⁻¹) comparisons, (2) applying dredge efficiency estimates from Table 5 to quantify these data, and (3) using diver samples that were inherently quantitative. Each of these datasets has strengths and weaknesses. The survey tow normally covered a swept area of 90 to 130 m². Such a sample integrates a large area of the bottom, but the sample is not inherently quantitative. Typically, data are expressed on a per-bushel basis as a consequence. Application of an efficiency correction permits quantification, but

also inserts an added degree of uncertainty. In this study, the influence of dredging during transplant seems to have varied dredge efficiency temporally, so that the correction factor varied over time. Diver samples are inherently quantitative, but cover a substantially smaller area; in this case, 3 m² per transect. The five diver transects, collectively, then, account for no more than about 17% of a single dredge-boat sample. Inasmuch as the limitations of each of these sampling methods tend to offset the others, we focused on cases in which the various methods reached corroborative conclusions.

Diver sampling revealed a significant reduction in oyster abundance as a consequence of the transplant, but this reduction could not be confirmed from the dredge samples. The reduction was greatest on the dry-dredge plots, because sampling was concentrated in those areas most heavily dredged and dredging impact was most localized on these plots. Size frequencies were not significantly altered, nor did condition index change more in one treatment type than another. The data suggest only a limited impact of the transplant activity on population attributes.

Sampling over the next 10 months revealed that average size increased and average spat number declined. Condition changed as would be expected by the seasonal cycle in condition (Hopkins et al. 1954, Haven 1962, Versar Inc. 2002). None of these changes occurred to a greater extent in any treatment. Evidence from diver sampling again suggests a differential change in oyster abundance between treatments over time. This trend is corroborated, though less clearly, by significant changes in clump cross-sectional area and the number of oysters per clump in the dredge-boat samples. The overall decline in oyster abundance is partly due to mortality, but also because spat settlement was low in the several preceding years. The significance of the time \times treatment interaction terms accrues from the tendency for oyster abundance and clump size to decline more in the controls than on the dredged plots; however, this, plus the rise in dredge efficiency previously noted, suggests that the August 2002, industry transplant may have impacted the control plots.

Overall, the transplant process had a limited influence on oyster population characteristics on any of the dredged plots, regardless of dredge type. The absence of impact is in keeping with other studies on the physiological effect of dredging on various shellfish, including oysters (Powell et al. 2001, Maguire et al. 2002, Kraeuter et al. 2003), though exceptions exist for more delicate species such as razor clams (Robinson & Richardson 1998).

Bed Complexity

The dry dredge as used for transplant must move a considerable amount of material around the bottom while retaining only a small proportion in the dredge. Presumably, bed patchiness would decline. The suction dredge, with its higher efficiency, should do the opposite. Bed patchiness should increase at a small scale. We examined two spatial scales, the within-diver-transect scale where samples were positioned 2 m apart and the between-diver-transect scale, using a number of measures of between-sample variance. Bed complexity did not change significantly by any measure during the transplant, nor did it change significantly over the subsequent 10 months.

Finally, we looked at the proportion of material contributed by cultch, the single and fragmented valves without live oysters or boxes attached. The concentration factors suggest that the suction dredge removes twice as much or more of this material than the

dry dredge. The proportional contribution of live oysters, boxes, and debris varied between treatments over time. This trend occurred because the volume of live oysters declined noticeably on control plots relative to either treatment over time, in keeping with other indicators that these plots were worked by the industry in August 2002. Cultch volume was not similarly affected, however. The expectation that cultch volume should be affected in some way led to a further examination of the variance between samples on a diver transect. The time \times treatment interaction term was not significant. No evidence exists that transplanting at the level tested in this study results in transient or permanent changes in bed complexity, whether the suction dredge or the dry dredge is used.

Fate of the Transplants

Between 1,000 and 2,500 bushels of material were placed on the New Beds experimental plots. This volume of material did not significantly elevate the abundance of oysters, as measured volumetrically. Evidence of the transplants does manifest itself, however, in a decline in clump cross-sectional area, an increase in the number of oysters per clump, and an increase in condition. Transplants from Cohansey had smaller maximum clump cross-sectional areas, typically 40–60 cm² rather than the pretransplant value of 71 cm², and more oysters per clump, 2–4 clump⁻¹ rather than 0.7 clump⁻¹ on New Beds prior to transplant. This is expected because New Beds oysters consistently average larger than Cohansey oysters (HSRL 2003) and these larger oysters increase clump size. Condition rose from 0.049 g dry wt (cm² shell area)⁻¹ to 0.052–0.068 g dry wt (cm² shell area)⁻¹, but this increase may be due to the elapsed time between sampling before and after transplant, rather than an influence of varying condition between Cohansey bed and New Beds.

Over the next 10 months, the number of oysters declined significantly as Dermo disease took its toll. Year 2002 had the highest natural mortality rate on New Beds and neighboring beds of any year since the incursion of *Perkinsus marinus* into Delaware Bay in 1989 (HSRL 2003). This mortality event affected both suction-dredge and dry-dredge transplants more or less equivalently. Neither condition index nor population size frequency diverged between the two transplant plots, though each varied over time as expected. Thus, to the degree that the sampling program could identify and track the transplants, the two methods of transplanting did not seem to produce divergent results in the fate of the transplanted oysters.

Economics of Transplantation

In this study, the dry-dredge boats loaded 1,053 bushels of material containing an estimated 67,866 market-size oysters at an estimated cost of \$1,579.50 at \$1.50 per bushel. The value per bushel is representative of the cost of industry transplants carried out in Delaware Bay, wherein boats involved in the transplant have received up to \$2 per bushel, depending on the year ([‡]NJDEP, pers. Comm.). The cost of suction dredging is less certain, the record being limited to a single recorded transplant event. In this case, the cost per bushel moved was \$0.70 (NJDEP, pers. comm.). Using this figure, the suction dredge loaded 2,635 bushels in this study containing an estimated 130,828 market-size oysters at an approximated cost of \$1,844.50. A bushel of oysters going to

market contains approximately 345 oysters (HSRL 2003). The dry dredge, therefore, transplanted 196.7 market-equivalent bushels downbay at a cost of \$8.03 per bushel and the suction dredge, 379.2 market-equivalent bushels at a cost of \$4.86 per bushel.

Both cost estimates are likely to be high, in comparison to a normal transplant program, because our Cohansey sites were not chosen to optimize the economics of transplant by targeting areas with the largest densities of market-size animals, and because we have not included in these estimates the survival and growth to market size of smaller oysters. Nevertheless, the comparison is illustrative. The increased efficiency of capture of larger particles by the dry dredge, even taking into account the slower speed at which this was accomplished, offsets in part the increased speed but lower catchability of the suction dredge. Nevertheless, the suction dredge remains about twice as efficient in purely economic terms as the dry dredge.

CONCLUSION

We tested the potential impacts of using a dry dredge and a suction dredge for transplanting at a level anticipated to be at or just above a sustainable level of removal. Over the short time span of a single transplant year, neither method proved deleterious either in its effects on bottom complexity, cultch availability, or population character.

Both dredging styles influenced subsequent dredge efficiency by a traditional dry dredge, probably by reducing bed cohesion, and this change was relatively long-term in duration in that dredge efficiency remained higher 10 months after transplant. However, the activity of dredging does not necessarily impact the oyster populations themselves. Powell et al. (2001) examined the influence of repeated dredging, but were unable to discern any increase in mortality or morbidity in the dredged population. None were detected in this study either. Thus, the increase in dredge efficiency is important in the context of quantitative sampling methodology, and possibly for the economics of fishing, but inconsequential biologically.

Advantageous use of the oyster resource on the upbay nursery beds has 3 requisites. (1) Large animals must be efficiently culled and moved downbay. (2) The upbay nursery beds must be managed to achieve sustainable yield, in this case, sustainable transplant. (3) The process must take place with limited long-term damage to the bed. Given the absence of impact on the portion of the population left on the bed and on bed complexity, these requisites distill to a single principle: market-size oysters should be concentrated during the transplant process, thereby minimizing the number of small oysters and amount of cultch moved downbay. Neither dredging method performed. The suction dredge as configured selectively removes smaller particles enriched in juveniles and cultch. The suction dredge makes inefficient use of the nursery beds and risks the potential for a long-term decline in live oyster abundance and shell coverage. The dry dredge, on the other hand, is inherently capable of concentrating larger animals and the on-deck culling device selectively retains the larger particles. Unfortunately, as used, much of the selective advantage of the dry dredge in transplant disappears. Conceivably, a behavioral shift in the dry-dredging process, by minimizing the time the dredge is left on the bottom, could retain the inherently desirable selectivity traits of the dry dredge in the transplanting process. This same

[‡] New Jersey Department of Environmental Protection

change could minimize the economic disparity presently enjoyed by the suction dredge.

ACKNOWLEDGMENTS

Special thanks to Sam Elias, Captain of the *F/V Howard W. Sockwell* and *F/V Jeanne Christine*, Lou Shultz, Captain of the *F/V Mabel Hollinger*, and Scott Sheppard, Captain of the *F/V Robert Bould*, for their participation in this study. Special thanks also to Royce Reed, Russ Babb, and Jason Hearon of the New Jersey

Department of Environmental Protection for providing vessel and diving support. We particularly thank the dive team headed by Joe Dobarro who collected the 1,080 diver samples that constituted the quantitative samples for this study. Thanks also to Heather Diviney, Bruce Muller, Jeff Gendek, and Allison Pesselano for help in sample analysis. This study was supported by an appropriation from the State of New Jersey through Rutgers University under the oyster stock assessment program managed by the Delaware Bay Section of the Shell Fisheries Council.

ORGANISMS ASSOCIATED WITH OYSTERS CULTURED IN FLOATING SYSTEMS IN VIRGINIA, USA

F. X. O'BEIRN,* P. G. ROSS AND M. W. LUCKENBACH

College of William and Mary, Virginia Institute of Marine Science, Eastern Shore Laboratory,
P.O. Box 350, Wachapreague, Virginia 23480

ABSTRACT The number and abundance of macro-faunal taxa was estimated from six floating structures (floats) used to culture the Eastern oyster (*Crassostrea virginica*) near Chincoteague Island, Virginia, USA. After a 10-mo grow-out period, all organisms found among and attached to the cultured oysters were counted. The final mean size of oysters was 80.5 (14.7 SD) mm. Overall, 45 species of macrofauna were recorded with the number of species in the floats ranging from 24 to 36. There was no relationship between the number of taxa and the density of oysters in the floats. Total abundances of associated organisms were estimated at 12,746/float to 92,602/float. These findings highlight the diverse (taxonomic and trophic) and abundant nature of communities associated with cultured oysters. They also provide a baseline set of information that may help more clearly define the interactions between oyster culture and the environment.

KEY WORDS: *Crassostrea virginica*, oysters, aquaculture, epifauna, floats

INTRODUCTION

A consequence of declining wild Eastern oyster (*Crassostrea virginica*) stocks throughout the eastern seaboard of the United States (MacKenzie et al. 1997) has been concerted efforts focused on oyster restoration (see Luckenbach et al. 1999a). Shellfish restoration throughout the United States is driven by a number of motives (e.g., ecological and fishery value) and typically involves a wide range of user groups (da Silva Pinho 2000, Breitburg et al. 2000, Brumbaugh et al. 2000, Mann 2000). One approach in support of shellfish restoration is the promotion of aquaculture (mostly of oysters) with the ultimate goal of reducing fishing pressure on wild stocks. During the culture process, oysters are subject to colonization by a variety of organisms. However, the number and relative abundances of taxa associated with the cultured oysters has rarely been assessed, as is the influence of the culture activity on the surrounding habitat. The primary goals of this study are, to identify and enumerate the number of taxa (macro-fauna >2 mm in size) associated with oysters (under culture conditions in Virginia) and to quantify the relative proportions of each taxa. Furthermore, it is hoped that these data will help define any ecological and environmental associations of oysters under culture conditions.

MATERIALS AND METHODS

Oyster culture in Virginia has three distinct stages. The first involves broodstock conditioning, spawning, larval culture, settlement, and an early nursery phase that is effected in a land-based hatchery. Upon removal from the hatchery, a field nursery phase follows where the oysters (3-mm shell height) are placed in mesh bags (2500 oysters per 61 cm × 61 cm bag, 1.5 mm mesh size). As the oysters increase in size, they are stocked in bags with increasingly larger mesh sizes (e.g., 1.5 mm to 3 mm to 9 mm bags) with a concomitant decrease in densities (2500 to 1200 to 600 or less oysters per bag, respectively). The majority of this nursery phase is conducted in off-bottom floating structures called oyster floats (Luckenbach et al. 1999b). The third phase or grow-out phase is conducted either in tray structures located on or near the bottom of

the leased area or in floats. The floats most commonly used are mesh baskets (mesh size = 2.54 cm) that are 2.5 m L × 0.6 m W × 0.3 m D. A polyvinyl chloride (PVC, 10 cm in diameter) collar is secured around the open part of the basket providing floatation for the system. A shade cloth cover is stretched over the top of the float to reduce algal fouling and predation of the single oysters in the floats from birds and mammals (e.g., seagulls and otters). Typically, the oysters are emptied directly into the float for final grow-out (1200–1400 oysters per float). This reduces maintenance associated with tending bags and reduces potential growth restrictions on the oysters, a consequence of confinement within bags. Grow-out typically extends from 8–14 mo. During this period, although the aquaculturist may remove the floats from the water to remove dead oysters, the oysters remain undisturbed until they are harvested.

Oysters for this study were cultured at a polyhaline site south (1 km) of Chincoteague Island, Virginia. In May 1998, oysters were removed from the hatchery at a mean shell height of 3 mm and as part of a field nursery phase were grown as outlined earlier. The grow-out phase commenced early September 1998. As part of another study, examining the effect of differential stocking densities on growth in the floats, three floats were initially stocked with 1750 oysters per float and three with 1000 oysters per float. Dead oysters were removed from the floats twice during the grow-out period (November 1998 and April 1999). After approximately 10 mo (mid June 1999), when it was expected that many of the oysters would be harvestable (at 76-mm shell height), sampling of the oysters and associated fauna took place.

Prior to removal of the floats from the water, a mesh basket (capture basket: 2-mm mesh size) was carefully placed in the water surrounding each float and the capture basket and float were loaded onto the support vessel. The purpose of the exterior basket was to retain any motile fauna that passed through the larger mesh of the float. All motile organisms captured on the exterior basket and located within the float were identified and enumerated. Sampling was effected by blindly selecting 50 oysters from all oysters (within each float) laid out in trays on the deck of the vessel. The shell height and width was measured for each randomly collected oyster. In addition, all attached faunal organisms were identified and enumerated. Colonial species were enumerated as a single

*Corresponding Author. E-mail: francis.obeir@marine.vi

representative of that organism. Total counts of live oysters in the floats were also calculated, thus allowing us to standardize the abundance of organisms in the float.

RESULTS

The final density of oysters cultured in the floats varied considerably and ranged from 488–1381 oysters per float, with an overall mean of 974 oysters per float (Table 1). The density disparity was most likely due to a combination of error associated with original stocking density and differential mortality of oysters in the floats. However, there was little relationship ($r^2 = 0.182$, $P > 0.05$) between oyster density and the number of taxa found in the floats (Fig. 1A). There was a slightly stronger relationship ($r^2 = 0.238$, $P > 0.05$) between the oyster density and the abundance of organisms in the float (see Fig. 1B). Shell height of oysters in the floats ranged from 76.17 to 83.52 mm, with an overall mean of 80.50 mm (see Table 1). The number of macrofaunal taxa in each float ranged from 24 to 36 with an overall mean of 29. In total, 45 faunal taxa were found in the oyster floats (Tables 1 and 2). These represented 11 broad taxonomic groups (see Table 2). The most abundant taxonomic group was annelids that comprised from 47.44% to 69.37% of organisms in the six floats. Mollusks comprised the next most abundant group (11.45% to 27.93%) followed by crustaceans (11.49% to 15.73%). Overall, in terms of abundance, annelids comprised 57.64% of all organisms, mollusks 20.01% and crustaceans 13.76% (see Table 2). These groups comprised 91.4% of all organisms sampled from the floats.

DISCUSSION

The total number of taxa (45) found among the oysters in this study was relatively high and compare favorably with the findings of previous studies of oyster communities (Wells 1961, Bahr 1974, Dame 1979, Larsen 1985, Stanley & Sellers 1986, Zimmerman et al. 1989). Meyer and Townsend (2000) recorded 41 species associated with newly constructed oyster reefs in North Carolina. However, many of these authors report on open reef structures relying on natural recruitment of oysters in mesohaline environments. Given the polyhaline character of the Chincoteague site used in this study it might be expected that the number of taxa recorded would be higher. That greater numbers of taxa were not recorded is likely a consequence of the fact that the assessment of associated organisms was carried out after only 10 months of potential colonization time in an enclosed structure suspended in the water col-

umn. In addition, this limited colonization time may have some bearing on the fact that certain species, typically associated with oysters in similar environments (e.g., the boring sponge, *Cliona celata*) were not recorded in this study.

Palmer et al. (1998) observed that little baseline data are available to serve as guidelines for restoring aquatic habitats. Not the least of these is species composition, from which community structure and trophic interactions may be evaluated. From our findings, a number of trophic groups are apparent in the culture systems. While filter feeders dominated (bivalves), others represented were detritivores (e.g., *Polydora websteri*, *Palaemonetes vulgaris*, omnivores (e.g., *Gobiosoma boscii*) and carnivores (e.g., *Callinectes sapidus*). The diversity of feeding types suggests the potential for various trophic interactions within the culture system and between the system and the surrounding habitat. Of course, limitations are imposed on the interactions by the meshing that comprises the floats. For example, larger predators (e.g., mature blue crabs, fishes, etc.) may be excluded. A potential limitation in interpreting the results of this study, imposed by the sampling methodology, is that smaller motile species (e.g., amphipods) may not have been retained by the 2-mm sampling mesh.

The dominance (in terms of abundance) of relatively few taxa is not unusual for shellfish assemblages. In this study, 3 groups of organisms (polychaetes, crustaceans, and mollusks) comprised 91.4% of all of the macrofauna sampled. Tenore and Gonzalez, (1975) observed that dense epifaunal assemblages (dominated by few taxa) were associated with cultured mussels in Spain. For wild oyster populations, O'Beirn (unpublished data) documented that numerically 94.6% of all faunal organisms found on a constructed oyster reef in Virginia were represented by four taxa. Seed and Suchanek (1992) and Lintas and Seed (1994) had similar findings

for faunal communities associated with the blue mussel, *Mytilus edulis*. It must be noted that, whereas numerical dominance (as assessed in this study) may be a useful indicator of community composition, species biomass (not assessed in this study) may

yield different conclusions regarding community structure that may be equally as important.

The occurrence of some species in the floats is of particular interest. The portunid crab, *Cronius ruber*, was considered rare in

Virginia (Van Engel & Sandifer 1972). However, in this study, five specimens, ranging in size from 24.9–34.9 mm, were located within the floats. These findings allied with previous and subsequent observations (O'Beirn personal observation), suggest that they are more than just occasional or rarely occurring species. The numerous fish species sampled highlight the importance of oysters as habitat for these species. Not only is the interstitial space among the oysters important, but dead articulated shells also provide useful habitat (in the form of refuge or nesting sites) for the blennies and gobies (Breithurg 1999).

The increase in aquaculture activities throughout the world has initiated much discussion and research on the interaction between the activity and the environment (Freeman 1988, Hickey & Hurst 1989, Iwama 1991, Hastings & Heinle 1995). Oysters may be cultured in areas that were previously devoid of the species. Hence, they could be regarded as an introduced species into a system. Simenstad and Fresh (1995) recommend that resource managers should consider the effects of aquaculture and attendant activities on ecosystem and community levels. The effects of introducing a large-scale monospecific culture operation into a particular system can have a cascading effect and ultimately affect production and the species composition inherent within the system (Simenstad & Fresh 1995). A shift in the ecological balance may affect the ability of the communities within the system to withstand perturbations of one form or another.

It has been suggested that shellfish culture activities benefit the environment by attracting numerous other organisms to the area (Dewey 2000). Whether they are truly an ecological or environmental benefit or not has yet to be specifically determined. The benefits (i.e., habitat and production) afforded by oyster culture activities may be minimal given the ephemeral nature of these communities (mediated by harvest and handling schedules). Many organisms constituting these communities may not actually mature

to reproduce. Consequently, these systems may be regarded as sink populations. In addition, certain associated species may actually compete with the culture organism for food resources (e.g., blue mussels and wild oysters setting on the cultured oysters; Adams et al. 1991), and increase the organic loading emanating from the culture systems (Nugues et al. 1996). Finally, as urbanization and human activities lead to an increase in habitat alteration in coastal areas (Connell 2000), suites of potentially competing organisms may be introduced into an area. Such a phenomenon may upset the ecologic balance of the area by changing the constituent organisms and species interactions within the system. As the scale of anthropogenic activities increase, it will be increasingly important to further elucidate these and other ecologic interactions.

A major impediment to successful restoration of impacted shellfish habitats is defining success of a particular venture (Coen & Luckenbach 2000). Defining goals and establishing success criteria has proven difficult, given that in many regions natural shellfish habitats (to use as reference locations) are lacking (Luckenbach et al. 1999a, and references therein). Anecdotal accounts of shellfish population structure and associated organisms in particular regions most often are insufficient upon which to base an expensive and long-term restoration program. Therefore, these data may give an indication (in terms of community assemblage and/or trophic interactions) of what may be expected when initiating an oyster restoration program.

ABSTRACT Studies of oysters, *Crassostrea virginica*, collected from 10 sites in the Caloosahatchee River and Estuary, Florida, revealed a varied parasite and symbiotic faunas that have never been reported in this area. Organisms observed included ovacystis virus infecting gametes at four sites (prevalence <1%), ciliate protozoans *Ancistrocoma* sp. in the gut of a stressed oyster at one site and *Sphenophrya* sp. infecting the gills of animals at three sites (prevalence <1%). The gregarine protozoan *Nematopsis* was found at all 10 sites (prevalence 24% to 90%) and oysters at some sites had concurrent infections of *Nematopsis pyrrherchi* and *Nematopsis ostrearium* in connective tissue near the stomach, mantle, and gills. Light to moderate infestations of hydrozoan polyps of a species in the genus *Eutima* were observed in the gills of oysters at all sites (prevalence 1% to 22%). Helminths included an unidentified turbellarian (prevalence 1% to 4%) observed at three sites and the digenetic trematodes *Echinostoma* sp., *Proctoeces maculatus* and *Bucephalus* sp. in oysters at five (prevalence 1% to 93%), three (prevalence >1%), and six (prevalence 1% to 3%) sites respectively. The first two trematodes were found infesting the gonoducts of their hosts while sporocysts of *Bucephalus* sp. infected connective tissues and gonads. Metacercariae of a species in the genus *Tylocephalum* were found in vesicular connective tissues near the gut, mantle, and in the gills of animals at all sites (prevalence 7% to 58%). Many sites had oysters with multiple infestations/infections of the above organisms indicating a rich biotic diversity, especially at those sites least impacted by human activity.

KEY WORDS: oysters, parasite, symbiont, prevalence, diversity

INTRODUCTION

Eastern oysters (*Crassostrea virginica*) are highly valued as food, but their ecological significance is under-appreciated and under-studied (Coen et al. 1999a). The oyster's ability to form large biogenic reefs (Coen et al. 1999b) qualifies it as a keystone or valued ecosystem component (VEC) species. VEC species are those that sustain the ecological structure and function of dominant estuarine communities. These species provide not only food, but also the physical habitat used by other organisms for living space, refuge, and foraging sites (Volety et al. 2003a). The complex 3-dimensional reef structure it forms attracts numerous species of invertebrates and fishes. To date, over 300 species have been identified as depending, either directly or indirectly, on oyster reefs (Wells 1961, Crabtree & Dean 1982, Abbe & Breitburg 1992, Wenner et al. 1996, Coen et al. 1999a) and many of these organisms in turn serve as forage for important fishery species (Tabb & Manning 1961, Marshall 1958, Gilmore et al. 1983) and birds (Watts 1988). Using a suite of responses from oysters, studies of the effects of heavy metals, organochlorine pesticides, rainfall, and freshwater releases into the Caloosahatchee Estuary from Lake Okeechobee on these animals were carried out. In addition, the effects of rainfall and freshwater releases on species abundance, richness, biomass, and diversity in Caloosahatchee oyster reefs were investigated. Data obtained from these studies will be used to assess the anthropogenic impact on the estuary and to provide target conditions for watershed management (Volety et al. 2003a, 2003b). One aspect of these studies, histologic examination of oysters, revealed a number of parasites and symbionts living in and on collected animals. Parasites have been used as an indicator species in environmental assessments for some time. There have

been a number of investigations on the effects of pollution and generalized human disturbance on parasites of fishes and mollusks to indicate anthropogenic impacts (Møller 1987, Khan & Thulin 1991, MacKenzie et al. 1995, Kuris & Lafferty 1994, Lafferty 1997). The most common approach is to compare the prevalence or intensity of parasitism among hosts sampled from a number of control and impact sites or a single site before and after the impact (Lafferty 1997). The rationale being that the diversity and presence of parasites, especially larval parasites and their intermediate hosts, can be potentially useful indicators of disturbances that reduce the abundance and diversity of vertebrates that act as the parasites' final host (Lafferty 1997). Thus, information regarding the presence or absence of parasites/symbionts in the Caloosahatchee estuary should be useful in assessing anthropogenic impacts when combined with all other aspects of the study. Therefore, the objective of this study is to report, for the first time, a survey of those parasites and symbionts observed in oysters from selected collection sites in the Caloosahatchee study area and briefly discuss how their presence or absence may indicate greater biologic diversity and a measure of ecosystem health.

MATERIALS AND METHODS

Sampling Locations

Oysters were examined from two projects being conducted within the same area of the Caloosahatchee estuary (Fig. 1) during a similar time period. The first project was designed to examine the effects of season and freshwater flow on the ecologic and physiologic processes of oysters as well as the habitat use of oyster reefs by fish and crustaceans. Monthly samples, 10 oysters per site (total 239 per site), were taken from 5 collection sites between September 2000 and December 2002. Sample sites included Piney Point (PP, 4 km upstream from the river mouth), Cattle Dock (CD, 2 km upstream from the river mouth), Bird Island (BI, 4 km downstream from the river mouth), Kitchel Key (KK, 6 km downstream from the river mouth), and Tarpon Bay (TB, 12 km downstream from the river mouth). The second project was designed to examine the

Funding for this study was made possible by grants from the South Florida Water Management District and the Charlotte Harbor National Estuary Program, Contribution No. 1206, of the Gulf Breeze Environmental Research Laboratory.

relationship between heavy metals, PCBs, and organochlorine pesticides measured in water and oyster tissues with the physiologic and ecologic responses of sampled oysters. Samples, 10 per site (total 78 to 90 per site), were taken from 5 sites every other month between June 2001 and December 2002. Sample sites included Iona Cove (IC, 4 km upstream from the river mouth), Tarpon Point (TP, 1.5 km upstream from the river mouth), Shell Point (SP, 1.75 km upstream from the river mouth), Port Sanibel (PS, 5 km downstream from the river mouth), and Greg's Reef (RS, 6 km downstream from the river mouth).

Histologic Analysis

Oysters sampled for histology were shucked and transverse whole-body sections (1–2 cm) were cut from immediately behind the labial palps to obtain a representative area of mantle, gills, gonadal, and digestive organs. These tissues were fixed in Davidson's fixative (Shaw & Battle, 1957) and prepared for paraffin sectioning. Sections (7 μ m) were stained with Harris' hematoxylin and eosin and examined via light microscopy for parasites and gonadal reproductive stages.

Data concerning the protist parasite *Perkinsus marinus* and relationships of agents described in this study with the compounds and environmental factors that were measured in the second study will be presented in more detail in a subsequent manuscript.

Definition of Specific Terms

Infection/infestation: "an infection is the invasion or state resulting from an invasion by a parasite or a pathogen into a host. An infestation is an external rather than an internal invasion. If both internal and external organisms occur on one host, all the associations are collectively referred to as infections. Neither an infection nor an infestation necessarily imply disease" (Overstreet 1978).

RESULTS

A polyoma-like virus was found in gametes (eggs) of oysters from Piney Point, Kitchel Key, Tarpon Bay and Port Sanibel stations (Table 1). The viral infection produced abnormal hypertrophied, basophilic ova ranging up to 250 μ m in diameter with scant cytoplasm (Fig. 2). Pathologic response to the condition was limited to a light to moderate hemocytic infiltration that may have been in response to lysis of affected ova. Prevalence was low (<1%) at all stations where the virus was found (Table 1).

A ciliate, *Ancistrocoma* sp., was found attached to the epithelium and free in the lumen of digestive diverticulum in one oyster from the Cattle Dock Station (Table 1). This oyster appeared to be undergoing physiologic stress from *Perkinsus marinus* infection with a significant hemocytic response to the *Perkinsus* and an epithelial lesion in the stomach (Fig. 3). Another larger basophilic ciliate, *Sphenophrya* sp., was found attached to gills of animals collected from Bird Island, Kitchel Key, and Tarpon Bay. This ciliate formed colonies sufficient enough to cause xenomas in all affected oysters (Fig. 4). Prevalence was low at all stations (<1%) and besides the obvious xenomas, no pathologic damage was observed.

Apicomplexan oocysts, *Nematopsis* sp. (Fig. 5) were found in connective tissue of the gills, mantle and digestive diverticulum at all collection sites sampled (Table 1). In some cases, oocysts found in the gills were larger than those in the mantle and digestive diverticulum of the oyster (19 \times 15 μ m vs. 13.4 \times 10 μ m respectively). Infections were light for the most part and no pathologic damage, other than tissue space taken up by the organism, was observed. Average prevalence was greatest at Tarpon Bay (92%, range 70% to 100%) and Piney Point stations (90%, range 20% to 100%) and lowest at Iona Cove (24%, range 0% to 70%).

Hydrozoan polyps of a species in the genus *Eutima* sp. (Fig. 6)

TABLE 1.

Prevalence of parasites and symbionts in oysters (*Crassostrea virginica*) collected from 10 stations within the Caloosahatchee River/Estuary study area. Values in parentheses represent prevalence (% of parasite/symbiont presence).

Figure 2. Light micrograph showing normal and virus-infected hypertrophied ova (arrow) in the gonad of an oyster, *Crassostrea virginica*.

were found infesting the gills of oysters at all collecting sites (Table 1). Polyps were attached to gill epithelium and most infestations appeared to be light to heavy (3–5 animals per histologic section). The hydroid's pedal disc did not appear to penetrate the oysters epithelium and no observable pathology was detected beyond possible obstruction of water flow to the gills. Highest prevalence was seen at Cattle Dock (22%, range 0% to 80%) and Shell Point (16%, range 0% to 80%) whereas Kitchel Key and Tarpon Bay had the lowest numbers (<1%).

An unidentified turbellarian (Fig. 7) was found infesting the gills of oysters at three stations (Table 1). Worms were closely associated with gill epithelia and infestations appeared to be light (1–3 worms per histologic section). These organisms had an elongate, ciliated body 0.081 to 0.162 mm (mean, 0.107) wide by 0.112 to 0.25 mm (mean, 0.17) long. The worms elicited a moderate hemocytic response in the oysters' gills and many became engulfed in copious mucous secreted from and surrounding the worm (see Fig. 7). Prevalence was greatest at Bird Island (4%) whereas Kitchel Key and Tarpon Bay were 2.5 and 1%, respectively (Table 1).

Figure 3. Ciliate infection (A), *Ancistrocoma* sp., in the gut of a stressed oyster, *Crassostrea virginica*. Note damaged epithelial lining of the gut (arrows) with concomitant hemocytic response to damage.

Figure 4. Ciliate infection, *Sphenophrya* sp., in the gills of an oyster, *Crassostrea virginica*, creating a xenoma, seen as numerous dark nuclei (arrows). Note normal gill tissue to the left and right. Insert (a) shows a higher magnification of 4. Insert (b) shows the beginning of xenoma formation in gills of a different oyster.

Large numbers of encysted metacercaria of a digenetic trematode species in the genus *Echinostoma* (Fig. 8) were found encysted in the gonoducts of oysters from five collection sites (Table 1). Morphologic features are similar to trematodes reported in oysters (*C. virginica*) from Tampa Bay, Florida (Fisher et al. 1996, Winstead et al. 1998). The helminths did not appear to cause any tissue damage but localized massive hemocytic responses to necrotic worms were quite evident (see Fig. 8). Average prevalence was greatest at Tarpon Bay (93%, range 20% to 100%) and Greg's Reef sites (56%, range 0% to 100%) and lowest (of those collection sites with the parasite) at Kitchel Key (1%, range 0% to 10%).

Unencysted metacercarial stages of another digenetic trematode species in the genus *Proctoeces* (Fig. 9) were found in the gonadal follicles and gonoducts of male and female oysters from Shell Point, Port Sanibel and Cattle Dock sites (Table 1). General morphologic features of the sectioned trematode are similar to *Proctoeces maculatus* described in oysters, *C. virginica*, from northern Gulf coast estuaries (Winstead & Couch 1981). Oysters

Figure 5. Oocysts of a species in the genus *Nematopsis* infecting the vesicular connective tissue in the gills of the oyster, *Crassostrea virginica*.

Figure 6. Polyps of a hydrozoan in the genus *Eutima* infesting the gills of the oyster, *Crassostrea virginica* (arrows).

showed no significant hemocytic or other cellular reaction to the worm. Also, even though the observed worms were surrounded by oyster gametes (see Fig. 9), there was no evidence of gonadal impairment to the oyster.

Sporocysts of a species of digenetic trematode in the genus *Bucephalus* (Fig. 10) were found in vesicular connective tissue of gills, palps, digestive diverticula, and in the gonads of male and female oysters from Piney Point, Bird Island, Kitchel Key, Iona Cove, Tarpon Point, and Port Sanibel (Table 1). Sporocysts contained numerous germ balls and developing cercaria (see Fig. 10). Many animals had heavy infections in which branching sporocysts of the parasite had completely destroyed the gonads by mechanical damage and physiologic decomposition of gametes. There was little host response to the presence of the worm except in instances where hemocytic reaction to dead or degenerate sporocysts was evident. Piney Point had the greatest prevalence (3%) whereas the other collection sites, where the parasite was observed, showed less than 1% infection.

Metacystodes of a species of cestode in the genus *Tylocephalum* (Fig. 11) were observed infecting vesicular connective tissue

Figure 7. Unidentified turbellarian infesting gills of oyster, *Crassostrea virginica*. Note moderate hemocytic reaction in gills and copious mucus secretion, filled with oyster hemocytes, surrounding the worm.

Figure 8. Encysted metacercariae of a digenetic trematode in the genus *Echinostoma*, in the gonoduct of the oyster, *Crassostrea virginica*. Note heavy hemocytic response to dead trematode in adjacent gonoduct (arrow).

in gills, digestive diverticula, and stomach at all collection sites (Table 1). Larval worms elicited a host response, which included a thick encapsulation consisting of a fibrocyte-like inner layer and an outer hemocytic response that appeared more severe around those worms closest to the stomach (see Fig. 11). Some of the parasites appeared to be undergoing resorption by the host. Also, many oysters had multiple infections of the parasite (see Fig. 11). Average prevalence of the worm was greatest at Tarpon Bay (58%, range 30% to 90%) and Greg's Reef (53%, range 20% to 90%) whereas Iona Cove (8%, range 0% to 30%) and Shell Point (7%, range 0% to 20%) had the lowest.

Concurrent infestations in many oysters by two to five of the parasites described earlier in the discussion were observed at all collection sites. This was especially evident at Tarpon Bay and Gregs Reef (Table 1) where many oysters had *Nematopsis* sp., *Tylocephalum* and *Echinostoma* sp. and some at Tarpon Bay were also infested with turbellarians and hydroid polyps.

DISCUSSION

The polyoma-like virus infecting the gametes of some Caloosahatchee oysters caused massive hypertrophy of infected eggs but,

Figure 9. Unencysted metacercariae of a digenetic trematode, *Proctoeces maculatus*, in the gonoduct of the oyster, *Crassostrea virginica*.

Figure 10. Sporocysts, filled with cercariae and germ balls, of a digenetic trematode in the genus *Buccaphalus* invading and replacing the gonad of the oyster, *Crassostrea virginica*.

other than a light to moderate hemocytic infiltration into localized areas where infected eggs were, did not appear to cause any significant pathologic response. This condition has been described in *C. virginica* from the Piscataqua River, Maine (Farley 1976) Long Island, New York (Meyers 1981) and the northeastern Gulf of Mexico (Winstead et al. 1998, Winstead & Courtney 2003). Similar lesions have been reported in *C. gigas*, *C. commercialis*, *Ostrea lurida*, and *O. edulis* (Farley 1978, Lauckner 1983). The condition has been termed "ovacystis disease" and is characterized by massive hypertrophy of ova and gametocytes, which contain Feulgen-positive (DNA) granular masses in the nucleus (Farley 1976, Winstead & Courtney 2003). Whereas normal ova reach a maximum of 75 μm in diameter (Galtsoff 1964), hypertrophied ova can reach up to 500 μm in diameter. Electron microscopy in the earlier cases revealed the presence of viral-like particles within the nuclei of hypertrophied cells. Prevalence of the condition was low and oysters showed little pathologic effects as was the case in the Caloosahatchee oysters.

The Ancistrocomid ciliates found in the gut of one oyster at

Figure 11. Metacystodes of a cestode in the genus *Tylocephalum* in the vesicular connective tissues of the oyster, *Crassostrea virginica*. Note the heavy fibrous encapsulation around larval cestodes by the oyster.

Cattle Dock Station were probably responding to the injured oyster as secondary invaders rather than as primary pathogens. The lesion in the oyster's gut concomitant with the heavy infection of *P. marinus* probably weakened the oyster and made it more susceptible to these invaders. Ancistrocomid ciliates have been reported in numerous bivalves from the Atlantic, Pacific, and Gulf coasts (Lauckner 1983). In the Gulf of Mexico, what were probably ancistrocomid ciliates have been reported infecting the gut and digestive diverticula in oysters from Pascagoula Bay, Mississippi, Mobile Bay, Alabama, Pensacola Bay, Florida (Couch 1985), and Louisiana estuaries (Mackin 1962, Gauthier et al. 1990). Couch (1985) and Gauthier et al. (1990) reported little pathology associated with these infections. However, Mackin (1962) concluded that these ciliates may become a complicating factor when oysters are infected with *Dermocystidium marinum* (= *Perkinsus marinus*) and Burton (1963) reported ancistrocomid ciliates associated with an abnormal histologic appearance of the host's tissues and unusual concentrations of hemocytes in "gaper" oysters from Chesapeake Bay, Maryland. The condition of the Caloosahatchee oyster, *Perkinsus* infection with massive hemocytic response to the parasite and an injury, appear similar to those in oysters described by Mackin (1962) and Burton (1963). This would lend credence to Lauckner's (1983) conclusions that ancistrocomids, normally gill parasites that cause little pathology to their host, in some cases become opportunistic and invade the host's tissues under abnormal conditions of physiologic stress.

Sphenophrya sp., ciliates induced the formation of xenomas in the gills of affected oysters. Some oysters had multiple infection sites in their gills. Infected epithelial cells contained anywhere from 3 to 4 to hundreds of ciliate nuclei per site. Aside from the possibility of occluding water tubules in the gills, no observable pathology was detected. *Sphenophrya*-like ciliates have been reported in the gills of *C. virginica* from the Atlantic coast (Newman 1971, Otto et al. 1979, Meyers 1981), and in the Gulf of Mexico, similar ciliates have been observed infecting the gills in oysters from Pascagoula Bay, Mississippi, Mobile Bay, Alabama, Pensacola Bay, Florida (Couch 1985), and coastal Louisiana (Gauthier et al. 1990). Sphenophryids are unique because when they occur in large numbers they can induce a distinctive lesion known as a xenoma (Weissenberg 1922). This condition ensues after one of the organisms enters a host cell and proliferates, stimulating the host cell to undergo repeated karyokinesis and massive hypertrophy to accommodate the numerous ciliates contained therein. Xenomas range from the size of a single cell to a macroscopic cell about 3 mm long (Otto et al. 1979) and, as discussed, this condition was observed in all the Caloosahatchee oysters found to be infected with the ciliate. The occurrence of these organisms, whether a single sphenophryid or in xenoma form, has not been reported to cause distress to infected oysters (Lauckner 1983).

The Caloosahatchee oysters exhibited a high prevalence of *Nematopsis* from most collection sites. Most infections were light and, aside from taking up tissue space in the gills or visceral mass, did not appear to cause any pathologic damage to their hosts. Many oysters had two different sizes of oocysts located either in vesicular connective tissue around the stomach and mantle or in the gills. Gregarines of the genus *Nematopsis* use *C. virginica* as a normal intermediate host and are quite common in many different species of bivalves along the Pacific, Atlantic, and Gulf coasts (see review by Lauckner 1983). More recent studies have reported the parasite in oysters from Pascagoula Bay, Mississippi; Mobile Bay, Alabama; Pensacola Bay, Florida (Couch 1985); coastal Louisiana

(Gauthier et al. 1990); Apalachicola Bay, Florida (Fisher et al. 1996); and Tampa Bay, Florida (Fisher et al. 2000). The presence of different size oocysts parasitizing a number of the same oysters at different sites probably indicates a concurrent infection by two different species of this protist. The smaller size oocysts from the Caloosahatchee oysters are probably those of *N. oostreum* because they are both similar in size ($\sim 10 \times 14 \mu\text{m}$) and are most conspicuous in the mantle and in connective tissue around the digestive diverticula, where *N. oostreum* are generally found (Sprague 1949, Lauckner 1983). Also, numerous mud crabs *Panopeus* sp. and *Eurypanopeus depressus*, which are the definitive hosts for this parasite (Lauckner 1983), were abundant at all study sites where the protist was observed (Volety et al. 2003a). The larger oocysts are probably those of *Nematopsis prytherchi* because they are similar in size ($\sim 19 \times 16 \mu\text{m}$), occur in the gills, and have been reported to occur concurrently with *N. oostreum* in *C. virginica* (Sprague 1949, Lauckner 1983). The definitive host for *N. prytherchi* is the stone crab *Menippe mercenaria* (Sprague 1949) which were also found at the Caloosahatchee sites sampled (Volety et al. 2003a). Reports concerning the pathogenicity of *Nematopsis* infections in *C. virginica* are inconclusive but most researchers have found no evidence to indicate the parasite is harmful to oysters (Overstreet 1978, Lauckner 1983).

The cnidarians observed infesting the gills of Caloosahatchee oysters did not seem to cause any pathologic distress to the hosts, even though large numbers of the symbiont were present in many of the collected animals. Several species of warm water hydrozoan cnidarians inhabit body folds of bivalve molluscs as inquiline symbionts. Of these, only one North American genus, *Eutima*, is found in *C. virginica* attached to the oysters gills, mantle and palps (Mulholland & Fredl 1996, Samler 2001). Those researchers collected oysters from numerous sites along the southern Atlantic and Gulf coasts and observed hydroids only in Florida from Tampa Bay and St. Augustine southward (Samler 2001). Thus, it is probable that the hydroids observed in the Caloosahatchee oysters belong in this group. The light to heavy infestations with no observable pathology detected is not unusual because prior studies of these hydrozoans reported that oysters can tolerate thousands of polyps without apparent harm (Samler 2001). Infestations appeared to have a seasonality because hydroids at those collection sites with the heaviest prevalence were observed in spring and early summer months (February to June) whereas almost none were detected in midsummer through fall. The summer decline was similar to other closely related bivalve-inhabiting cnidarians, *Eugymnanthea inquilina*, observed in mussels and clams from the Ionian Sea, Italy (Piraino et al. 1994) and Japanese waters (Kubota 1983). Kubota (1983) reported a summer decline in hydroids from Japanese waters noting that polyps became very small, and often degenerated, at the end of medusoid production. In addition, Samler (2001) reported hydroid numbers in Florida waters declined rapidly following large drops in temperature or salinity after heavy summer rains. Experiments determined critical temperatures and salinities for these hydroids to be between 10 and 33°C and 8‰ to 34‰ respectively (Samler 2001). A drop in salinity occurred in the Caloosahatchee study sites during the summer months of the study. Salinities, which averaged 31‰ during most of the study, dropped to under 10‰ at most sites and to less than 5‰ for weeks at each occurrence, especially at Cattle Dock and those collection sites close to it, where the hydroids were most prevalent (Volety et al. 2003a, Volety et al. 2003b).

The turbellarians found infesting the gills of Caloosahatchee
